4. As to the mathematical development of the final working formula (omitting the correction for errors), it may be noted that the author has given two equations, Nos. (42) and (43). Equation (42) is theoretically the final form in which the variation in the coefficient of torque due to variation in the voltage of the needle has been taken into account. Equation (43) is a simplified practical final form of equation (42), assuming the coefficient of torque to be constant and independent of voltage. In the several experimental demonstrations given by the author, this coefficient is either really constant, the working voltage having been maintained constant for each series of tests, or practically constant and regarded as such by the author himself. In other words the final working formula is equation (43), not (42). In view of this fact, it may be of interest to know that equation (43) can be derived directly from the well-known fundamental equation, that is, from equation (11) of Prof. Kouwenhoven, without the intermediate thirty equations which needlessly discourage an average reader. I do not intend to suggest that equation (42) together with the mathematical development which leads to it, is all unnecessary. It is easy to believe that occasions will arise where the nature of the work in hand calls for a

1. The Quadrant Electrometer for the Measurement of Dielectric Loss, by D. M. Simons and W. S. Brown, A. I. E. E. JOURNAL, December 1924, page 1147.

variation of voltage, which would make equation (42) indispensable. In view of this possibility, I might suggest that Prof. Kouwenhoven extend his experiments to the case of varying voltage, other variables being maintained constant for the time. It would be interesting to have it demonstrated that the coefficient of torque follows the law formulated in equation (42).

W. B. Kouwenhoven: The quadrant electrometer is an electrostatic instrument and measures root-mean-square values exactly. Its readings are independent of wave form and frequency. The capacity-load measurements referred to in Table VI were made with energy supplied from a generator that does not give a pure sine wave. Under these conditions the current wave was badly distorted; nevertheless, the results checked closely. I am sure that the instrument could be successfully used in measuring core loss in iron samples.

As stated in the paper, equation (43) is only a special case of equation (42). Equation (43) may be directly derived from Maxwell's equation (11).

In using an instrument it is always desirable to have a straight-line constant, but this is not possible in all electrometers for the reasons mentioned in the paper. In some electrometers the constant varies considerably with the needle voltage. In the electrometer referred to in the paper the constant varied as follows:

Needle Voltage	55 volts;	Constant	72	Table	V
" "	100 "	"	71.8	"	IV
" "	400 "	"	69.7	"	VI

This electrometer was used later with voltages as high as 1800 volts on the needle. At this voltage its constant was found to be 33.8. This clearly shows the effect of the variation in voltage upon the constant of the instrument.

A New Method and Means for Measuring Dielectric Absorption

BY RALPH E. MARBURY*

Associate, A. I. E. E.

Synopsis.—*The progress of practically all electrical apparatus is to a large degree dependent on progress in insulation. The successful selection and use of insulation, particularly insulation operated with maximum economy as in the case of static condensers, depends on our progress in the understanding of the factors on which insulation quality depends.*

It has long been known that for a given working condition, reliability depends on dielectric losses, particularly the losses commonly referred to as hysteresis losses.

The hysteresis loss is definitely related to the phenomenon of absorption or residual charge, especially when the residual voltage quickly builds up.

In order to further analyze dielectric losses, and study the progress of treatment of insulation, a device has been developed for measuring dielectric absorption.

This article describes the "Dielectric Lag Meter" and gives some test data secured by it.

* * * * *

I. Introduction

The importance of insulation to the progress of the electrical art is well recognized. This is especially so in apparatus where insulation is operated with maximum economy, as in the case of condensers and cables. Possibly the most important of all insulation from the standpoint of relation to the cost and reliability of the apparatus is that used in condensers, since in condensers the insulation is the vital element, the active part, and fundamental to the device itself. More than that, the quantity of insulation varies inversely as the square of the stress at which the material is worked. The working stress must at all times be well within limits which have been established as reliable; nevertheless as we acquire knowledge of the fundamentals of insulation, we shall be able to fabricate it more economically and operate with less, but more definite, factors of safety.

Insulation may be divided into two general classes; viz., (1) that occurring in a natural state, (2) that which is created by combination of other materials. Under the first class we have mica and similar substances, while under the second class we have fibrous spacer materials impregnated with oils, waxes, or similar substances. The practical disadvantage of the first class is that the quality is not under our control. We can only make suitable tests to select the material of satisfactory quality. Insulation of the second class, while of a complicated nature, is subject to closer control since practically all the materials making up the structure may be controlled to a greater or lesser degree. It is only necessary to exercise the proper control when a means is available by which the quality of the various materials can be studied separately, combined, and during the process of combination.

The advantages of oil-impregnated paper insulation are now fully recognized and this type of insulation has been used with success for many years. This form of insulation can be used in large quantities due to its inherent uniformity. A closer control, however, during impregnation, will result in still greater gain, since a

*Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

large mass of insulation may be treated until every unit of its volume is of satisfactory quality. The principal advantages of oil-treated paper insulation are the high quality of oil as an impregnating medium, the circulating or heat distribution qualities, and the thoroughness with which it impregnates the material.

It is extremely important that practically all the moisture be removed from the paper before the introduction of oil, and, in fact, the characteristics of the dielectric consisting of high grade paper and oil depend almost entirely on the completeness of moisture removal before impregnation.

Many methods have been developed whereby the finished condenser, or cable, may be tested for dielectric losses. Such tests are extremely important, especially when one is concerned with the efficiency or temperature rise. On the other hand, these tests give only the result of imperfections and not the nature of the losses. In other words, the losses in the condenser may be caused by losses in the metal plates, conduction losses, or the so-called hysteresis losses in the dielectric itself.

It is desirable not only to analyze these losses but to make the tests on the condenser during treatment.

In the case of 60 cycles, practically all of the loss is in the insulation itself, rather than in the metal plates or due to conduction through the dielectric. It is generally agreed that the losses in the insulation are directly related to the phenomenon of absorption. A measure of absorption during treatment should serve as a very effective quality control.

A device for conveniently measuring absorption has been worked out and it is the purpose of this paper to describe this device in detail.

II. Dielectric Absorption

When a condenser having a perfect dielectric is connected to a source of electromotive force, it immediately takes up a quantity of electricity, Q_0, which is proportional to the voltage

$$Q_0 = C_0 E$$

where C_0 is the geometrical capacity, or the capacity based on the physical dimensions of the insulation and specific inductive capacity.

However, in the case of an imperfect dielectric, the above does not complete the process. The quantity Q_0 increases with time until a final value, Q_∞, which exceeds the value Q_0 by a certain fraction K, is reached.

$$Q_\infty = (1 + K)\, Q_0 E$$

This characteristic of insulation has been given the name of dielectric absorption and the key to an understanding of insulation losses lies in the thorough understanding of this phenomenon.

As stated above, the initial quantity of electricity may be represented by Q_0. This is also the quantity that will be dissipated on a quick short circuit or discharge through a low resistance. Thus, when a condenser is charged, discharged, and then left open-circuited, a voltage will build up with time across its terminals. The rate at which this voltage builds up, and the magnitude of the voltage for a given condenser, depends on the time of charging and applied voltage. With different condensers, the shape of this residual curve, especially when different applied voltages are considered, depends on the quality of the insulation.

Our work has indicated that these curves, if fully understood and analyzed, will provide a measure of at least the major factors on which dielectric quality depends.

The most desirable method for measuring absorption direct is to charge the condenser for an arbitrary, but short, length of time, then discharge it through a very low resistance to eliminate the quantity Q_0, and measure the residual voltage as it builds up after discharge.

The subject of dielectric absorption has occupied the minds of many investigators over a long period. There are some who account for it entirely on the basis of heterogeneity, while others consider it of a more complicated nature.

F. W. Grover* has reviewed a number of these theories and analyzed them quantitatively.

K. W. Wagner† has made a careful study of the Maxwell‡ theory of absorption and has applied it to a more complicated dielectric structure.

Difficulty of Measuring Absorption

Many investigators have measured absorption by charging the condenser, discharging it, and immediately connecting across its terminals an electrostatic voltmeter. This is not wholly satisfactory, since the static voltmeter has a large time lag and fails to indicate the values of voltage during the most important part of the residual-voltage curve. Our tests of this kind showed that the part of the residual curve occurring during the first ten seconds is not secured. Further investigations showed first, that the most important part of the residual voltage curve occurs within the first second, and secondly, that after a few seconds the true shape of the residual curve is distorted by leakage current due to the over-all insulation conductivity.

It is desirable, therefore, to make the absorption measurements within one second after discharge, and a sufficient number of measurements should be taken during this period of time to establish with reasonable accuracy the shape of the curves.

The Dielectric Lag or Absorption Meter

The dielectric lag meter measures the instantaneous values of voltage across the condenser by direct comparison with known voltages.

The apparatus consists of an arm switch rotating at a constant and known speed, a potentiometer for varying the value of the known voltage, a galvanometer circuit, and a means for selecting the instant of time at which the measurement is to be made.

The diagram in Fig. 1 shows the rotating arm switch with twelve stationary contacts, the galvanometer and potentiometer circuits, and, in addition, a variable resistance in parallel to the condensers. The variable resistance is not used in making residual voltage curves, but is provided for making discharge curves which are described later.

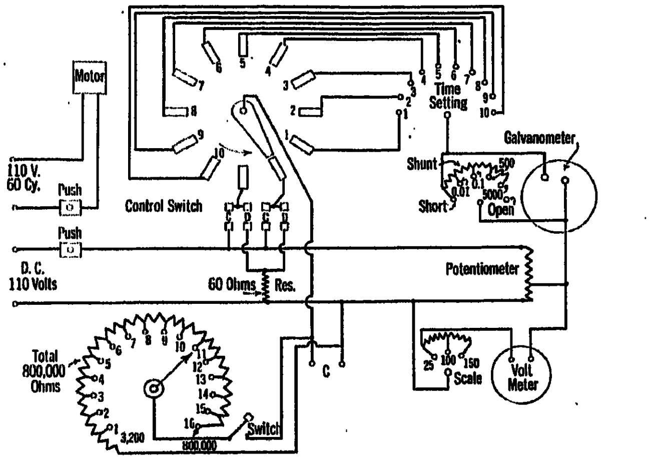

FIG. 1—DIAGRAM OF CONNECTIONS OF DIELECTRIC LAG METER

Three different types of test which may be made by means of this instrument have been found to be of particular value:

A. *Residual voltage against time,*
B. *Residual voltage against applied voltage,*
C. *Discharge curves with condenser and resistance.*

The methods of making these tests are discussed separately and in detail to illustrate the operation of the instrument.

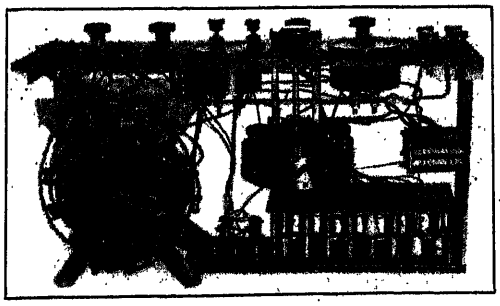

FIG. 2—INTERNAL VIEW OF DIELECTRIC LAG METER

A. Residual Voltage Against Time. The condenser to be tested is connected at terminals marked *C* in Fig. 1. The shunt resistance is disconnected for this test. The two terminals marked *D. C.* are connected to a source of direct current. The other two terminals are connected to the 110 volts, 60 cycles, for operating the synchronous motor driving the arm switch.

Two segments are used for charging and discharging the condenser, while the other ten segments are used for measuring the residual voltage at various values of time after discharge.

The charge and discharge segments are connected to the line and discharge resistance, marked 60 ohms on Fig. 1, by means of the switches *C, D, C, D,* so that when the arm is rotating counter-clockwise the first segment will charge the condenser to the applied voltage and the second will discharge it. The width of the charging segments and the space between it and the discharge segment are such as to fix the charging time at 0.111 seconds. The discharge resistance is made just high enough to prevent damage to the segments on the discharge and not high enough to fail to discharge the initial quantity Q_0.

In making the tests, the arm makesc ontact first with the charging segment, then with the discharge segment, and then makes a complete revolution and charges again and so on at a constant rate. Each time the arm leaves the discharge segment and as it makes its revolution a residual voltage develops each time taking on the same values for the periods of time corresponding to the segments 1, 2, 3 to 10, consecutively.

While this is going on, the time-setting switch, shown

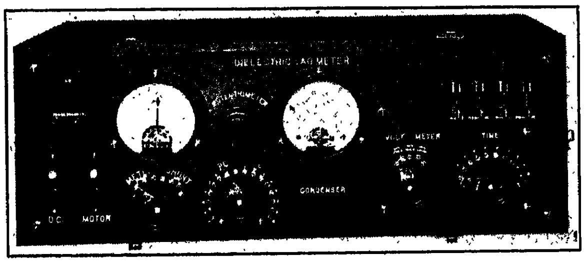

FIG. 3—FRONT VIEW OF DIELECTRIC LAG METER

on diagram Fig. 1, is set on contact one and the potentiometer voltage adjusted until the potential of segment No. 1 is the same as that of the rotating brush at the particular instant of time that it comes in contact with segment No. 1. This condition is obtained by adjusting the potentiometer until the galvanometer fails to reflect in either direction, when the arm makes contact with this segment. When the balance is obtained, the voltage setting of the potentiometer is equal to the condenser voltage at the instant of time corresponding to the position of segment No. 1, which is located 0.111 seconds after discharge. This is repeated for segments 2, 3, 4, etc., thus giving 10 points on the residual curve, 0.111 seconds apart.

B. Residual Voltage Against Applied Voltage. In this case the time-setting switch is left in some one position and the residual voltage measured for different applied voltages by balancing with the potentiometer as in *a.*

C. Discharge Curves with Condenser and Resistance.

Discharge curves are less important than the residual voltage curves, since more factors are involved. The departure of the curve on a condenser from the theoretical equations

$$E = E_0 \times e^{-\frac{T}{rc}}$$

is quite noticeable with the slightest amount of absorption. This is especially true with discharge curves of very short duration and the lag meter is especially suited for making these discharge curves.

In making discharge curves, the charge and discharge segments are changed so that the condenser is first discharged and then charged to line voltage. This is accomplished by means of switches C, D, as will be seen by referring to Fig. 1. In this case the condenser voltage is that of the line voltage when the arm starts its revolution and drops during the course of the revolution, due to the discharge resistance which is shunted across it. The variable discharge resistance should be set at a value depending upon the capacity of the condenser, so that the voltage at segment 10 will be of the order of one volt, thus giving 10 points on the discharge curve. Steeper discharge curves may be made, if desired, where the voltage has already reached practically zero value at segment two or four or even one. The values of voltage for segments from one to ten consecutively are determined as before.

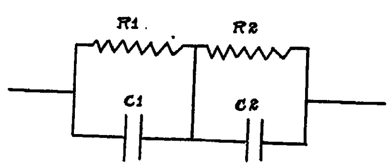

FIG. 4—MODEL CONDENSER TO ILLUSTRATE MAXWELL'S THEORY OF ABSORPTION

The details of the device, especially the arm switch, are shown in Fig. 2. The front with all control knobs is shown in Fig. 3.

DIELECTRIC ABSORPTION MEASUREMENTS WITH "LAG METER"

Three types of test are described below to illustrate the performance of the device:

1. Dielectric absorption tests on a model condenser made to illustrate Maxwell's theory of absorption.
2. Dielectric absorption tests on a paper condenser during removal of moisture to show effect of moisture removal on absorption.
3. Tests on miscellaneous power condensers.

1. MODEL CONDENSER

Clerk Maxwell showed in his famous Treatise on Electricity and Magnetism that a dielectric having a variation in the product of R and C at varous points would exhibit the phenomenon of absorption. That is, the initial voltage distribution would follow the values of C and a later or final distribution would follow the values of R. If the distribution according to values of R does not agree with the distribution for the values of C correspondingly, a shift will take place in the stored charges. This charge represented by the shift from the normal condition will not come out instantaneously when the condenser is discharged, but will come out with time after discharge, resulting in a residual voltage.

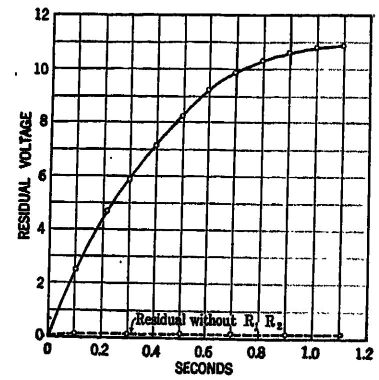

FIG. 5—RESIDUAL VOLTAGE AGAINST TIME FOR MODEL CONDENSER SHOWN IN FIG. 4

A model condenser was constructed to illustrate this, and measurements of the residual voltage were made with the lag meter. This model consisted of two condensers C_1 and C_2 shunted by a resistance R_1 and R_2 as shown in Fig. 4. No attempt was made to make the values representative of an actual condenser. The two condensers used to make this test had extremely low residual voltages, so that for all practical purposes the residual values obtained were due only to the fact that $R_1 C_1$ was not equal to $R_2 C_2$. Tests were also made with values of R_1 and R_2, so that the two products $R\,C$ were equal and no residual voltage was obtained in excess of that which would exist without the resistances.

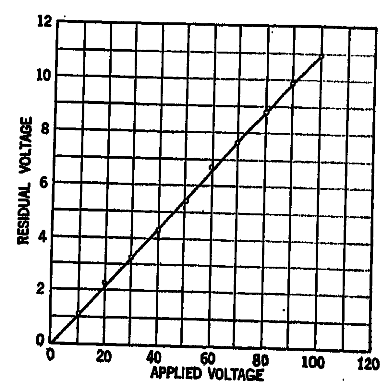

FIG. 6—RESIDUAL VOLTAGE AGAINST APPLIED VOLTAGE FOR MODEL CONDENSER SHOWN IN FIG. 4. TIME AFTER DISCHARGE EQUALS 1.11 SECONDS

The residual voltage against time for the model as shown in Fig. 4 is given in Fig. 5.

The residual voltage against applied voltage for T after discharge = 1.11 seconds, is given in Fig. 6.

This shows that the residual voltage is proportional to the applied voltage for such a model as would be expected from Maxwell's equations.

Fig. 7 shows discharge curves made, using the above model and with resistances of 31,000, 50,000, 135,000,

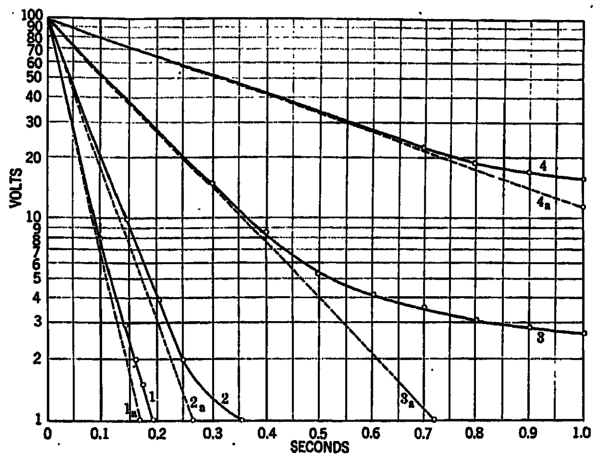

Fig. 7—Shows Discharge Curves Made Using Model Fig. 4

and 400,000 ohms. The model follows qualitatively Maxwell's theory of absorption.

2. Dielectric Absorption Tests on Condensers During Treatment to Remove Moisture

A stacked paper condenser having a capacity of approximately 3 microfarads was dried in an oven with vacuum in order to remove moisture, in accordance with

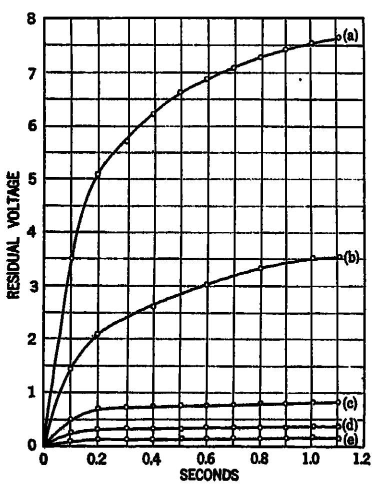

Fig. 8—Residual Voltage Against Time on a Condenser During Moisture Removal

the usual process. Five residual voltage curves were taken, one just after heat treatment before vacuum was applied and the other four during heat treatment with vacuum. In each case the condenser was allowed to cool to 22 deg. cent. before making the test. The five curves in Fig. 8 are identified as follows:

a. Heated the day before 6 hours at 60 deg. cent.

b. Heated the day before 6 hours at 100 deg. cent. and 27 in. vacuum.

c. Heated the day before 6 hours at 100 deg. cent. and 28 in. vacuum.

d. Heated the day before 6 hours at 100 deg. cent. and 28 in. vacuum.

e. Heated 16 additional hours at 100 deg. cent. and 28 in. vacuum.

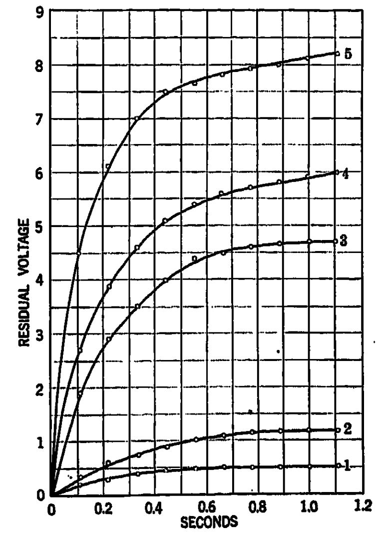

Fig. 9—Residual Voltage Curves on Typical Power Condensers

As the moisture is removed from the dry paper condenser, the residual voltage decreases to a value which is practically immeasurable, as shown by the above curves. This is due to the fact that the dry paper has very little absorption in itself.

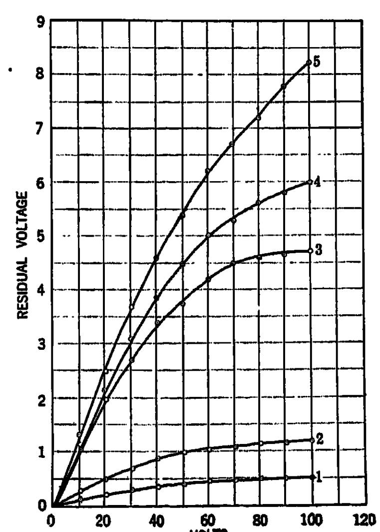

Fig. 10—Residual Voltage Curves Against Applied Voltage for Typical Power Condensers

3. Tests on Miscellaneous Power Condensers

In order to illustrate the values of residual voltage obtained with average commercial power condensers, curves are given in Fig. 9 for five different condensers, each of the same style but varying somewhat in quality. These curves show that for a very high

quality condenser, having losses of about 0.2 per cent as designated by Curve No. 2, the residual voltage is very low, while for a condenser having power losses such as 0.5 per cent the residual voltage is very much higher, as shown in Fig. 8, Curve No. 5. It must be borne in mind, however, that a direct comparison cannot be made between losses and residual voltage unless all factors are taken into consideration, and in fact, the exact relation existing has not been definitely established. These tests are made on 5-kv-a., 2300-volt condenser units.

Fig. 10 gives the five residual voltage curves against the applied voltage for the same condensers as covered by Fig. 9. Corresponding numbers are given to the two sets of curves for comparison.

It is of greatest importance to note that in Fig. 10 the residual voltage curves against applied voltage have a saturating characteristic, that is, at some voltage for each condenser the residual voltage reaches a maximum value or approaches a maximum value as a limit, instead of being at all times proportional. It is of even more interest to note that the higher the quality of the condenser, the smaller the angle of rise becomes.

Conclusions

All tests to date indicate that the residual voltage against applied voltage and residual voltage against time are of greatest value.

The saturating characteristics of residual voltage against applied voltage appear to be the most important of all, in that it follows so closely the over-all quality of the condenser and it is our opinion that a thorough understanding of this curve will result in a better understanding of the factors on which insulation quality depends. This saturating characteristic is not accounted for by previous work or theories, so far as we have been able to learn.

The immediate value of the absorption test is in determining when the moisture has been removed from the paper during treatment, so that in no case will the oil be applied until the moisture has been removed.

A measure of absorption may show the progress of the oil in reaching the microscopic crevices of the fiber.

After the factors affecting the absorption are understood, absorption tests may be of value in periodically testing cables in service, to show stratified deterioration and serve as a means of anticipating cable failures.

Discussion

J. B. Whitehead: We have not had sufficient recognition of the importance of dielectric absorption as a factor in the question of dielectric loss. Modern theory of dielectric behavior, such as it is, is directed more and more toward the explanation of dielectric loss in terms of dielectric absorption. That is not to say, however, that we are getting to understand the fundamental character of this loss any better, because there is no more obscure phenomenon than that of dielectric absorption.

We have Maxwell's theory of absorption, but Maxwell's theory has not been confirmed by quantitative measurements, and, indeed, there are many indications that it must be modified

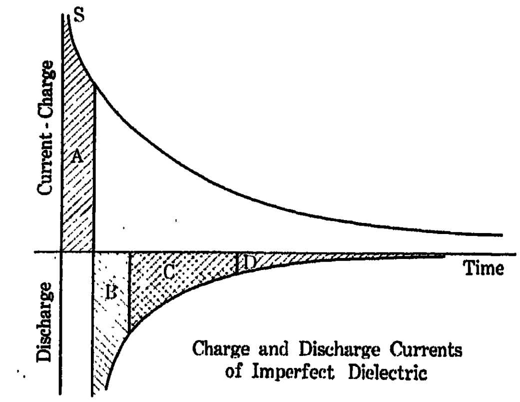

Fig. 1

in some way. However, the actual phenomenon itself is relatively simple; that is to say, we can make certain measurements on dielectrics which will give us certain curves, and if we express these curves in terms of mathematical functions it is possible to substitute these functions in our simple a-c. power equations and we get expressions for dielectric loss, phase difference, and specific conductive capacity, which go far toward explaining their variations with such quantities as voltage, frequency, and to somewhat less extent, the temperature. So it is particularly important that we should have a paper on this subject.

I find, however, in considering Mr. Marbury's method that it is subject to one very serious limitation. One of the best ways of representing the phenomenon of absorption is to plot a curve as in Fig. 1 between the charging current of the condenser containing the dielectric and the time; that is to say, if we take a condenser which has been lying idle a long time, and suddenly apply a continuous voltage, measuring the current, we find a curve approximately asymtotic to the axis of time, but which, in most cases, reaches a final steady value. In a few very perfect dielectrics only does the curve come down to the horizontal axis. This curve can extend over a very long period of time, days or even months.

For example, in 60-cycle circuits, we have complete reversal of voltage in a very short interval of time and consequently any influence of this absorption curve must pertain to a portion of the curve which is extremely near its starting point, *S*. The great trouble that has been found in linking up the phenomenon of absorption with losses as we observe them has been the dif-

ficulty of determining the shape of this curve for extremely short intervals of time.

In the cycle represented by Mr. Marbury's instrument, he charges the condenser for 1/10 sec., the quantity of charge being represented by the area A of the figure. He then discharges it for about the same interval of time (1/10 sec.), the quantity discharged being shown by area B. Now, there is a law not very generally spoken of, connected with this phenomenon of absorption. This is called the "Principle of Superposition." It was first noted by Sir John Hopkinson in some of the earliest and best work that has ever been done on dielectrics, and it was confirmed beyond question by J. Curie. It states that if you start one of these absorption curves, and then make any change, whatever, in voltage, the succeeding behavior of the dielectric will be as though you superimposed upon the initial curve the curve represented by the change of voltage when acting alone. In the figure, this means that when dielectric is short-circuited it behaves just as though we had applied a negative value of the voltage equal to the charging voltage. The discharge curve is exactly similar to the charging curve, but refers to the charging curve instead of the horizontal axis. In other words, it says the preceding state of the dielectric persists with the change in voltage applied to the initial curve, and not to the horizontal axis. So, also, the discharge curve which Mr. Marbury gets is subject to the same law.

But what does he do? He has discharge for only a period of 1/10 sec. and then allows the residual voltage to rise for a period of 9/10 sec. but then he stops! His voltage residual due to the first cycle is represented by the progressive integration of the area C; that is, all the residual due to areas B and D are not included.

If the discharge interval stops before the dielectric is completely discharged, represented by the full area under the discharge curve, he has not measured his residual voltage accurately. The observations he makes appertain to the particular cycle represented by his instrument, because his next charging cycle rises to a lower value and the successive discharge curve will also be a little less; but something more will be added to the foregoing residual. He is measuring the sum of a succession of these intervals, each one being less than the preceding one. So he is measuring something that is certainly due to absorption, but it is peculiar to the particular cycle he is using; namely, 1/10-sec. charge and discharge and a 9/10-sec. residual. The 1/10-sec. interval is of no great interest because it is not short enough for information as to 60 cycles. Hopkinson's investigations showed that a condenser, so far as the initial static charge is concerned, will be discharged in an interval in the order of a 1/17000 sec., the residual curve then starting. So in Mr. Marbury's instrument the discharge interval allows a large portion of the absorption to escape in the short circuit.

I am sure that Mr. Marbury's instrument will be of great value in testing the relative absorption properties of dielectrics, particularly those in which most of the discharge will take place within the interval of the instrument itself, but I think it ought to be clearly understood that it does not measure the true absorption curve and that what it measures is peculiar to this particular instrument.

Arnold Roth: It is interesting to note the different opinions on the importance of the losses in cables. We have worked on this question in Europe and our cable manufacturers also used to give much importance to this factor.

I should like to point out the difference in the importance of these losses in two kinds of materials, namely, (a) cable with relatively moderate outside temperature, (about 40 deg. cent.), and (b) materials which I should like to call "high-loss" materials, like bakelite, shellac, paper, etc., in oil of high temperature (70 to 80 deg. cent.). The importance of the losses for those two kinds of materials from the practical point of view is quite different.

To make it clear, I should like to speak of two kinds of breakdowns. On one side we have what we call the "real electrical" breakdown. It is known to all of us. It occurs in one-minute tests, one-second tests, or 1/10-second tests. Its physical details are not explained. On the other side there is another kind of breakdown which I should call "heat breakdown" or "loss breakdown." It was explained by Steinmetz, Wagner, Dreyfuss, and others, and is based only on the specific losses and the heat conductivity. You will remember that in insulating materials there are losses, and the losses increase very fast as the temperature increases. If you have some kinds of material and apply a voltage, it will create losses and the losses are transformed into heat. The heat makes the temperature rise, and you may reach a balanced state or an unbalanced state, depending entirely upon the voltage impressed.

This effect might be illustrated by the curves in Fig. 2 herewith, representing losses plotted against time. Curve E_1 refers to a voltage E_1; Curve E_2 to a somewhat higher voltage E_2. The object measured might be a bushing of the paper type (with or without condenser layers). In the first case, an equilibrium is reached after some hours; in the second case breakdown occurs.

It is possible to predict the voltage at which this breakdown occurs before having made any tests, provided you know the specific losses of the material and the heat conductivity. An accuracy of 10 to 15 per cent is possible. I say that in order to show that this phenomenon is not simply an assumption but that it is a calculable fact.

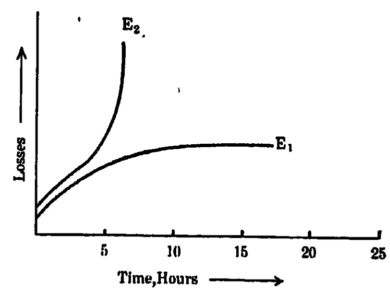

FIG. 2

Now, to get back to the point from which I started: I repeat that there are two kinds of breakdown voltages which may exist, namely, the heat breakdown voltage, due only to the losses, and the electrical breakdown voltage which, so far as known today, has no direct relation to the losses. In your cables, you have now very low losses and if you calculate the heat breakdown voltage for cables, you will see that you will come to about 180,000 volts in sustained service. You will see that today this heat breakdown voltage is of no importance whatsoever in connection with cables.

I do not wish to be misunderstood. Although the direct effect of the losses does not enter into consideration, that does not mean that loss measurements are of no importance. Loss measurements do give very interesting indications about moisture, regularity of manufacturing processes, and so on.

The heat breakdown voltage is quite another thing in bakelite. You are using it in hot oil in transformers; it may be at 60 to 90 deg. cent. In addition there are the specific losses of the material itself, so that you get there a limiting voltage of 60 kv. It might vary from 40 to 70 kv. You may be astonished because I apply such high voltages to bakelite. In speaking of those breakdown voltages, I am speaking of the case where you have only a unidirectional flow of heat. In a bushing you may have a dissipation of heat in the direction of the axis also, and the tension will be higher than that.

You see now that the electrical breakdown voltage for the cable is below this heat breakdown voltage and so the heat breakdown voltage is not of interest for cables. But it is quite a

different thing for bakelite. For bakelite the electrical breakdown voltage is above 60 kv., so the heat breakdown voltage is interesting. I know very many cases of commercial design where the heat breakdown is the governing factor.

Delafield DuBois: Mr. Marbury's paper, and Fig. 8 in particular, add to the data that we already have linking absorption, dielectric phase difference, and dielectric loss with moisture. Now the behavior of moisture in a dielectric under electrical stress, and particularly in a fibrous dielectric, is a most complex phenomenon. The moisture is strongly held by surface tension but is acted on by electrical forces tending to form it into conducting paths. Complicating this is the fact that the passage of current through these paths tends to disrupt them by heat generated in the paths.

If we had a dielectric containing a high resistance path embedded in it and partially bridging it, we would have the equivalent of the model condenser shown in Fig. 4 of the paper, and such a model would give a residual voltage curve as given in Fig. 6. But if this conducting path were a path of moisture it would not remain a fixed path of constant resistance, but would be constantly changing in length and resistance and interconnections with other moisture paths under the application and removal of voltage, and we should no longer expect a curve as Fig. 6. There are so many factors affecting this change that it is difficult to give them all proper weight in drawing conclusions. But, referring now to Fig. 10, it would seem that above a certain voltage the moisture paths, if we may consider them such, tend to increase in their effective resistance, acting to improve the dielectric. It is as if the dielectric became dryer with the increase of voltage.

It is obvious that for a higher voltage the conducting paths carry more current, and it does not seem unlikely that it is this current, dispersing the moisture paths, that is responsible for the shape of the curves of Fig. 10.

W. F. Davidson: Mr. Marbury's paper calls our attention to a very important phase of insulation behavior and one which gives promise of telling much about the fundamental behavior of electrical insulating material. The paper also presents a very interesting shop method for determining certain aspects of dielectric absorption, but I think it would be a mistake to classify the method as truly scientific.

Towards the end of the paper the author calls attention to an apparent saturation of the dielectric. In an effort to explain this we find a disconcerting lack of detailed information as to the apparatus used and the test procedure. For instance, the diagram of connection indicates a 110-volt d-c. supply for charging the condenser and we are without information as to the means used for varying the voltage in the individual tests. If this is done by means of a series resistance, certain results would be expected, while if it is done by varying the voltage of a battery with low internal resistance, the results would have a somewhat different characteristic. Furthermore we have no exact data as to the duration of the contact, either for the purpose of charging or for the purpose of discharging the condenser. An effort to determine this time by scaling from the drawing indicates that the contact has a duration in the order of 0.03 seconds, which can hardly be considered as a quick short circuit. Neither can the 60-ohm resistance be placed in the discharge circuit, be called low resistance, although it is quite permissible to use this sort of method for shop work.

In the early part of this paper the author referred to the "inherent uniformity" of impregnated paper, but I fear that his statements are somewhat misleading and a little too optimistic. Those of us who have had experience with high-voltage cable with impregnated-paper insulation fully realize that this material does not have an inherent uniformity; if it did have, many of the difficulties of the cable manufacturer would be things of the past. I must also question the thoroughness with which oil impregnates the material, for numerous observations have indicated that the thoroughness of impregnation depends in a very large measure on the type of fibre from which the paper is made. Probably Mr. Marbury's statement is quite correct for the type of paper used in manufacturing condensers, but it is hardly correct for some sorts of paper which have been suggested for use in high-voltage cable.

In the last paragraph of his paper the author makes the prediction that a study of absorption may afford a means of predicting cable failure in operating systems. A method of cable testing based upon this idea was described before the Institute in 1923 by Messrs. Phelps and Tanzer[2] and had been further developed by several operating companies. In a discussion of a paper on testing cable by Mr. Lee[3] presented at the Midwinter Convention of this Institute several aspects of the problem were discussed. Special high-speed, curve-drawing instruments for recording the data were described and some of the results presented.

Due to the large amounts of energy involved, the "discharge and recovery system" such as used for small condensers is very difficult to handle on long cable. Better results seem to be obtained by observing the characteristic during the period of charge. In addition to the advantage just mentioned for the charging system as distinguished from the discharge and recovery systems, there is the point that the readings are somewhat less influenced by the previous history of the cable. This is of great importance since the absorption of many of our cables is of very large magnitude and unless long times are allowed to elapse between successive tests the readings on any one test may be largely influenced by the preceding test value.

Probably the value of Mr. Marbury's paper could be very considerably increased if he could include some data taken with a electrostatic oscillograph showing the voltage across the condenser terminals during a complete cycle of the test, that is during the charge, the standing, the discharge, and the recovery periods. Such data would be very helpful in explaining the apparent saturation of the dielectric previously referred to. It would also give a better idea as to the behavior of the contacts and the effectiveness of the discharge circuit in removing basic quantity of electricity on the basic charge.

W. B. Kouwenhoven: The device developed by Mr. Marbury possesses many valuable features. It is similar in certain respects to the apparatus developed by the Bureau of Standards for charging and discharging condensers by the method of mixtures.[4] All who have used this apparatus know that different results will be obtained when the time of the charge, mix and discharge cycle is varied in any manner.

Mr. Marbury in his paper mentions the operation of his device at only one speed. It would be valuable to know what results would be obtained with some other cycle of charge and discharge and perhaps it would be possible to find some speed which will give results that would indicate more definitely the relative values of different types of insulating materials.

W. A. Del Mar (communicated after adjournment): A century and a half ago, Franklin made a Leyden Jar with removable coatings and found that the charge adhered to the glass and not to the coatings. Until three years ago this experiment was regarded as proof that the electric charge was held by the dielectric. In 1922, however, Addenbrooke upset this theory by repeating Franklin's experiment but taking special precautions to keep the surfaces of the glass absolutely dry, when he found that the charge adhered completely to the metal coatings. (*Phil. Mag.* 1922, Vol. 3, pp. 489 to 493). In Franklin's experiments, the charge which appeared to be in the glass was really bound to the moisture films on the surface of the glass.

There is moisture within most insulation and it can hold charges when the coatings are discharged. They would dissipate slowly through the high resistance of the dielectric, giving rise to residual-charge effects. It is therefore not necessary to assume the movement of moisture to explain dielectric absorption. The moisture merely acts as secondary or internal electrodes.

Mr. DuBois explains the effect of moisture by assuming that it collects in threads, stretching between electrodes, absorption being due both to the mechanical energy required to build the threads and to their influence in promoting the Clerk-Maxwell effect by shunting parts of the dielectric. If this were correct, the presence of moisture in sufficient quantities to produce distinct absorption effects should materially lower the breakdown voltage due to the short circuiting of parts of the insulation by these moisture filaments. This, however, is not the case, as tests with manila-rope paper impregnated with petrolatum show a distinctly higher dielectric strength when the paper is not dried prior to impregnation than when it is dried.

Research work is now needed to determine definitely whether the Clerk-Maxwell effect holds quantitatively in the absence of moisture and whether the added effect of moisture can be explained quantitatively by internal charges. If not, it will be time to look into the more complex theories that have been suggested.

E. S. Lee (by letter): The methods of measurement of residual voltage are of long-time standing. The particular feature ascribed to Mr. Marbury's instrument is that readings are obtained at intervals of 0.1 sec. up to 1.1 sec. after the condenser has been discharged. The means adopted for doing this excludes the usual caution that the condenser must be entirely discharged so that no residual charge remains for succeeding voltage applications. For this reason it would appear that results obtained by the instrument described by Mr. Marbury would be a function of the instrument constants.

Although not specifically stated, it would appear that the curves in Figs. 8 and 9 are obtained on comparable condensers. On the basis of this assumption it is interesting to note that the residual-voltage characteristics of an untreated-paper condenser during the drying (Fig. 8) are practically identical with the residual-voltage characteristics of treated-paper condensers having values of power factor from 0.2 per cent to 0.5 per cent (Fig. 9). From a standpoint of voltage rating and effectiveness of operation, the untreated-paper condensers would in no wise compare with the treated-paper condensers. The similarity of residual-voltage characteristics for such dissimilar insulations indicates the limitedness of the residual-voltage curves as a criterion for the effectiveness of insulation.

While claims are made by Mr. Marbury that all tests to date indicate that the residual-voltage curves are of the greatest value, it is interesting to note that while nothing new is pointed out by the author resulting from these curves, there is a correlation made between these curves and the values of power factor of the condensers measured. It would appear, therefore, that the correlation between the residual-voltage curves and the life of the insulation is not different from what we now know as between power factor and life.

R. E. Marbury: There are of course many causes of insulation losses, such as conduction losses, losses in the metal plates, and the so called hysteresis loss. The magnitude of the various losses depends a great deal on operating conditions; for example, on extremely high frequency the $I^2 R$ losses in the metal plates might be of great importance. On commercial frequencies such as 60 cycles the hysteresis type of loss is of greater importance, since the other losses can be reduced to neglible figures very easily. There is every indication that at least the most important cause of this hysteresis effect is absorption.

The long-transient residual curves have been observed for many years. It is quite common to receive a severe shock from a condenser after repeated attempts to discharge it. Maxwell's theory of absorption explained these long transients very well, and many investigators have plotted the residual voltage against time over long periods such as minutes, hours or even days after discharge. It can be easily shown mathematically that a condenser will develop these residual voltages if the products $R\ C$ for the various layers of insulation are not constant.

It has been recognized for a long time that the residual phenomenon of this type could not account for 60-cycle losses, due to the short duration of charge on 60 cycles, and that if 60-cycle loss was to be explained on this basis the same form of phenomenon would have to occur at a high rate of speed. The latter would require some very low products $R\ C$ as compared with the values capable of producing the common type of residual curves. In view of this, other more complicated theories of absorption were conceived, most of them admitting an actual lag in polarization. It is quite possible that there is a lag of this type but on 60 cycles it must be so slight as to be beyond measurement, and relatively unimportant from the point of view of losses.

While the model condenser may be only a rough approximation of a real condenser it may be used to a good advantage in discussing the phenomenon. Maxwell's theory is very useful. A model condenser such as shown in Fig. 4 of the paper will give a residual curve as shown in Fig. 5. If the values R_1 and R_2 are increased, the time required for the residual to reach its maximum value increases. The time required for the model to reach its steady state on charging also increases. The values R_1 and R_2 may be varied over unlimited range but the nature of the residual curves will be always the same. If we use an actual condenser, which in reality is composed of many such models in parallel, and charge it for a long time, we will obtain a residual curve which may require hours to build up to its maximum value. If we repeat this, using shorter and shorter charging time, we will find that as the time of charging is reduced the residual reaches its maximum value sooner. As long as we can continue reducing the charging time and obtain the same form of residual curves we are apparently correct in assuming that the cause of the residual is the same. Since the condenser is composed of many values $R_1\ C_1$, or $R_2\ C_2$, and since it is easily shown that the smaller these products the more rapid is the residual transient, it naturally follows that as the charging time is reduced the lower products $R\ C$ participate the most in producing the residual curves. The same may be said for long charging intervals until the charging time is long enough for the steady state to be reached for the largest products $R\ C$. If the charging time is augmented beyond this point the residual curve will not be affected.

The dielectric lag meter was developed to measure the residual curves with very short charging periods. The work that has been done has shown that the residual curves thus obtained are of the same type as with longer charging, thus proving that there are in a dielectric products $R\ C$ which are low enough to explain 60-cycle losses, and that the only difference between these residual curves and those heretofore obtained is that they build up very quickly, as is to be expected.

The principle of Maxwell's theory need not be modified. However, certain secondary phenomena do exist. The resistivity does not remain constant with voltage apparently due to movement of moisture under the influence of the field. Furthermore, the lines of force are not always perpendicular to the various materials, or to the metal electrodes, but become refracted in passing through media having different specific inductive capacities.

Dr. Whitehead spoke of the inability of the lag meter to record the entire or true residual curve. If Dr. Whitehead considers the true residual curve as that which would be obtained if the condenser remained on charge until a steady state is reached, then the lag meter will not measure it. Such a residual would require hours to develop, and the charging time would be of the same order. As stated above, the special object in view in the design of this device was to measure the residual that may be

secured with very short charging periods, or where the residual obtained is a function of low products R C.

In the paper the charging period mentioned in several illustrations is 1/10 sec. It was not intended that this figure be considered as important, as the charging time may be varied over a wide range during any investigation. The duration of discharge may also be varied depending on the data desired.

Dr. Whitehead mentions the effect of previous charge on residual curves, or in other words the "past history" of the dielectric. It is a fact, as can be readily shown, that if a dielectric is subjected to a routine charge and discharge a cyclic condition is quickly reached where the residual curves will repeat themselves very accurately for each charge and discharge, and the effect of previous charge disappears. With the lag meter this cyclic condition is reached long before the first reading can be taken, and in any case the galvanometer could not be balanced until this condition existed.

A graphic check on the results that may be obtained in so far as accuracy is concerned may be shown as follows:

Take the case of a model condenser such as shown in Fig. 4, but having the following values:

C_1 = 1.89 microfarads, C_2 = 3.11 microfarads,
R_1 = 796,000 ohms, R_2 = 4000 ohms.

It would be desirable to use for C_1 and C_2 perfect condensers, that is condensers having no residual of their own; otherwise the formula would not hold perfectly. The condensers used were not perfect but had a residual which was small compared to the residual caused by the model.

If we charge this condenser for a time T at a voltage V_o, the voltage being applied instantaneously, and then discharge it through an infinitely small resistance, the connection being left for an infinitely short time, we find mathematically that the residual voltage V at any time t after discharge follows the formula

$$V = V_o \frac{R_1 C_1 - R_2 C_2}{(C_1 + C_2)(R_1 + R_2)} \left[1 - e^{-\frac{T}{(C_1 \times C_2)} \times \frac{R_1 + R_2}{R_1 R_2}} \right] \left[e^{-\frac{t}{(R_1 c_1)}} - e^{-\frac{t}{R_2 c_2}} \right]$$

Calculating the residual on the above basis and using 100 volts for V_o and 0.07 sec. for T we obtain the dotted curve shown herewith in Fig. 3.

The solid curve in Fig. 3 was made on the same model using the lag meter but with a discharge resistance of 10 ohms left on for 0.0003 sec. If the two condensers C_1 and C_2 had been ideal condensers the curves would have practically checked.

Mr. DuBois states that the moisture films are elongated by the field sufficiently to bridge a part of the dielectric. He states that the current probably disrupts these paths and causes the unproportionality of residual to applied voltage.

It might be added that while this phenomenon may exist under certain conditions there is a movement of moisture that takes place very quickly. Probably the moisture movement that causes the shape of curve Fig. 10 in the paper is of a different nature from that Mr. DuBois has in mind. To illustrate this Fig. 4 is given herewith. This shows five residual curves made on the same condenser but with different charging times from 0.0014 sec. to 0.07 sec. When the charging time in this particular case exceeded 0.0035 sec. the curve took on a saturating shape. This became quite marked at a time of charging of 0.0065 sec., and the curve became almost horizontal with a charging time of 0.07 sec. This shows that a certain time is required for the moisture movement to take place. It is even more interesting to note that Curves A, B, C, D, E, may be made in any order and the same curves obtained, or any one curve may be made with increasing or decreasing voltage. This shows the wonderful accuracy of movement of the moisture, and suggests a movement within the limit of the surface-tension restoring force, rather than an extensive elongation and volatization as suggested by Mr. DuBois. If the condition exists as described by Mr. DuBois it would probably not repeat itself so accurately.

In reply to Mr. Davidson, residual-voltage curves as shown in Fig. 10 of the paper are made as follows. As far as balancing is concerned the lag meter is operated in the same way as when taking a residual curve as it builds up with time. The time-setting switch is left on one point and the residual thus obtained for this given time after discharge is plotted against applied

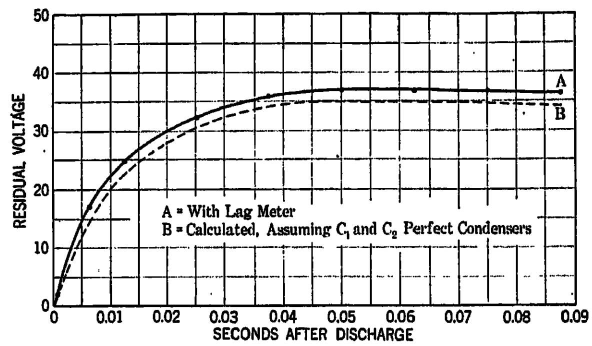

FIG. 3

voltage. Another way of course would be to run complete residual curves as in Fig. 9 for different applied voltages, then take the residual values corresponding to any desired time and replot against applied voltage. The same curve would be obtained of course in either case. The applied voltage was varied by means of a three-point rheostat having such characteristics as not to affect the results. If there were an effect of this kind the straight line as in Fig. 6 could not be obtained, nor would the straight lines as in Fig. 4 herewith be possible.

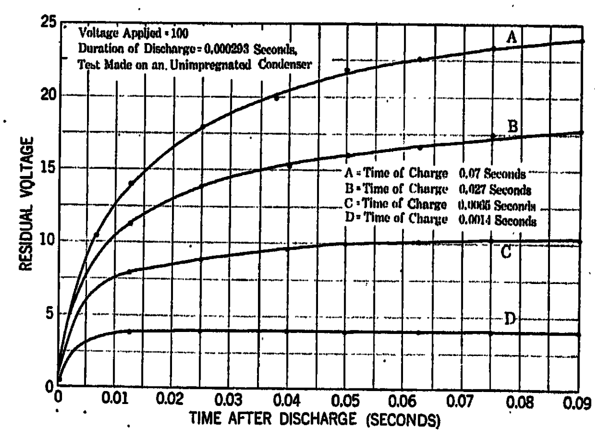

FIG. 4

Mr. Davidson mentioned the difficulties experienced in attempting to test cables by the charge-and-recovery scheme, owing to the large amount of energy handled. With the lag meter it is possible to read residual voltages as low as 0.1 volt with accuracy. There is no need, therefore, to use more than 100 volts. The lag meter works very satisfactorily on condensers having capacities as high as 10 microfarads. By slight adjustments it works equally as well on 100 microfarads.

Mr. Davidson asked how one could be sure that the discharge resistance was of the proper value, or if the discharge time was correct. This paper was written to describe the principle of measurement rather than the actual details and physical nature of absorption. It is possible that we may later have some

thoughts to offer on the subject of absorption in the light of data being obtained. Shortly after the contact drum described in the paper was made, a new drum was made which made possible

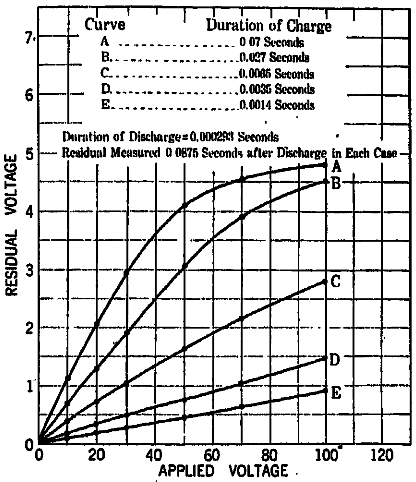

Fig. 5

a wide range of variation of time of charge, discharge, and the values of time following discharge were made smaller. This new drum was arranged so that the first point on the residual curve was only about 0.00035 sec. after discharge. This made it possible to observe at once if the condenser was discharged to practically zero.

In reply to Mr. Kouwenhoven regarding the speed, the speed may be changed at will by changing the worm-gear ratio on the driving mechanism. The speed which has been found of greatest value is such as to permit a charging time of 0.0025 to 0.07 sec.

Mr. Delmar refers to some of the more complicated theories of absorption, many of which assume an actual lag in polarization. Maxwell's theory will hold wherever the product $R\,C$ is not the same throughout the entire mass of material. We have only to show that in a dielectric there are products $R\,C$ low enough to cause or explain 60-cycle losses. The lag meter has proven the existence of low products $R\,C$ by the fact that with it, it is possible to record residual curves which build up to their maximum value in short spaces of time. Fig. 5 herewith gives a few such curves which show definitely the existence of such a condition.

Mr. Lee has called attention to the comparison between curves Fig. 8 and Fig. 9, stating that the residual is as high on the impregnated condenser as before. The statement that a condenser having power losses of the order of 0.5 per cent has higher residuals as shown by curve No. 5 Fig. 8 is incorrect. It should read Fig. 9. No comparison can be drawn directly between Figs. 8 and 9, as far as values of residual are concerned. Curves 1, 2, 3, 4 and 5 of Fig. 9 bear a relation to 60-cycle losses.

Separate Leakage Reactance of Transformer Windings

BY O. G. C. DAHL[1]
Associate, A. I. E. E.

Synopsis.—The paper discusses a method for determining the separate leakage reactances of transformer windings, originally suggested in 1921 by W. V. Lyon.[2] The method is applicable only to three-phase banks of three identical transformers, and makes use of the third harmonic electromotive force and current which are introduced into the windings by the inherent magnetizing characteristics of the iron. Attempts made to determine the separate leakage reactances of a single transformer did not meet with success.

The method may be used both with "two-winding" and "multi-winding" transformers. However, it is particularly convenient when the transformers have more than two windings.

Laboratory tests have been made on small experimental, two-winding and three-winding transformers, and field tests on a bank of three-winding power transformers. The results in each case warrant the conclusion that the separate leakage reactances may be obtained with sufficient accuracy for engineering purposes.

Introduction

The separate leakage reactances of transformer windings cannot be calculated with accuracy. The standard formulas found in textbooks on principles and design of transformers are all based on broad assumptions in regard to the distribution of the leakage flux, and may easily give results which are in error to a considerable extent. Furthermore, it seems to be doubtful whether more rigorous and reliable formulas are capable of being developed.

So far, no method has been available for experimental determination of the individual leakage reactances. It is easy to obtain the equivalent leakage reactance by a short-circuit test, but when it comes to assigning proper fractions of this reactance to the separate windings, difficulties are encountered. Usually the equivalent reactance is split equally between the two windings. This procedure, however, is frequently far from correct although often the only one which can be resorted to.

The purpose of this paper is to present a method, originally suggested in 1921 by W. V. Lyon,[2] by which the separate leakage reactances of transformer windings may be determined experimentally. This work was done as an introduction to a general study of transformer harmonics undertaken in the Electrical Research

1. Instructor Electrical Engineering, Mass. Inst. Tech., Cambridge, Mass.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

2. Massachusetts Institute of Technology.

Laboratories of the Massachusetts Institute of Technology.[3]

The theory of the method is briefly discussed and data and results as obtained from tests on three small experimental transformers are given.

The method has also been applied with success to a bank of three 2100-kv-a., 110,000/22,000/2300-volt transformers.[4]

Conception of Leakage Reactances

The mutual flux in an iron-core transformer is usually considered to be exclusively confined to the core. This assumption is not entirely rigorous. Evi-

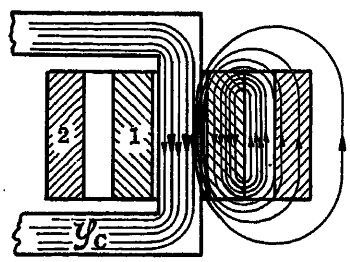

Fig. 1—Flux Distribution (Very Approximate) When the Inner Coil (1) Carries Current

dently part of the flux which the current in any one coil sets up in the air will produce linkages with the other coils and hence be a mutual flux in the true sense of the word.

All fluxes which have their entire path in air are proportional to the current producing them. This is true also for fluxes which only partly exist in the air, since the reluctance of the iron path is insignificant as compared to the reluctance of the air path.

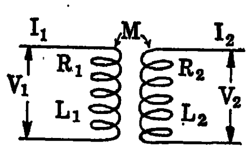

Fig. 2

Fig. 1 roughly illustrates the fluxes when the inner coil (1) carries current. As seen, a small part of the flux set up in the air will link with turns of coil (2) and produce a voltage in this coil in addition to the voltage produced by the flux in the core. This additional voltage will be in time quadrature with the current in coil (1).

Fig. 2 represents a two-winding transformer with both windings carrying current. Considering voltages and currents of a *single frequency* only the vector equations for the voltage drops in the two windings may be written:

$$V_1 = R_1 I_1 + j\,\omega L_1 I_1 + j\,\omega M_{12} I_2 \qquad (1)$$

$$V_2 = R_2 I_2 + j\,\omega L_2 I_2 + j\,\omega M_{21} I_1 \qquad (2)$$

Since the permeability of the iron is a function of the instantaneous flux density and hence of the instantaneous current, the self and mutual inductances will be some function of the current. On the contrary, the inductances which are due to fluxes in the air will be constant.

The flux in the core itself contributes the part, M_c, of the mutual inductance. Introducing this quantity, the two equations above may be rewritten in the following form:

$$V_1 = R_1 I_1 + j\,\omega\,(L_1 - M_c)\,I_1 + j\,\omega\,(M_{12} - M_c)\,I_2 + j\,\omega\,M_c\,(I_1 + I_2) \qquad (3)$$

$$V_2 = R_2 I_2 + j\,\omega\,(L_2 - M_c)\,I_2 + j\,\omega\,(M_{21} - M_c)\,I_1 + j\,\omega\,M_c\,(I_1 + I_2) \qquad (4)$$

In equation (3), $L_1 - M_c$ is a *constant* inductance due to all the flux in the air set up by the current in coil (1). It is the "self leakage inductance" of this coil. $M_{12} - M_c$ is the constant "mutual leakage inductance" of coil (1). The term $j\,\omega\,M_c\,(I_1 + I_2)$ evidently represents the voltage induced in coil (1) by the flux which exclusively exists in the core. The corresponding quantities in equation (4) may be similarly interpreted with reference to coil (2).

Introducing

$$X_{11} = \omega\,(L_1 - M_c) \qquad (5)$$

$$X_{22} = \omega\,(L_2 - M_c) \qquad (6)$$

$$X_{12} = X_{21} = \omega\,(M_{12} - M_c) = \omega\,(M_{21} - M_c) \qquad (7)$$

$$E_{1c} = E_{2c} = j\,\omega\,M_c\,(I_1 + I_2) \qquad (8)$$

equations (3) and (4) reduce to

$$V_1 = E_{1c} + (R_1 + j\,\omega\,X_{11})\,I_1 + j\,\omega\,X_{12}\,I_2 \qquad (9)$$

$$V_2 = E_{2c} + (R_2 + j\,\omega\,X_{22})\,I_2 + j\,\omega\,X_{21}\,I_1 \qquad (10)$$

Neglecting the exciting current, the primary and secondary currents are equal and opposite and the equivalent impedance drop $V_1 - V_2$ becomes

$$\begin{aligned} V_1 - V_2 &= [R_1 + j(X_{11} - X_{12})]\,I_1 - [R_2 + j\,(X_{22} - X_{21})]\,I_2 \\ &= (R_1 + j\,X_1)\,I_1 - (R_2 + j\,X_2)\,I_2 \\ &= [\,R_1 + R_2 + j\,(X_1 + X_2)\,]\,I_1 \\ &= (R_e + j\,X_e)\,I_1 \end{aligned} \qquad (11)$$

The reactances, X_1 and X_2, are the true leakage reactances of windings (1) and (2), respectively, with respect to the other winding. The relative aspect of the leakage reactances should be carefully noted. The leakage reactance of a winding is not a quantity which is dependent upon and characteristic of that winding alone; it must, of necessity, be defined with respect to some other winding. This fact becomes particularly important in multi-winding transformers. Thus in a transformer having three windings designated Nos. 1, 2 and 3, the leakage reactance of winding No. 1 with respect to winding No. 2 will be in general different from the leakage reactance of the same winding with respect to winding No. 3.

3. Some results of these researches have been incorporated in the author's report, "Transformer Harmonics", published in the report of the Inductive Coordination Committee of the National Electric Light Association in June 1923.

4. See the paper "Transformer Harmonics and Their Distribution."

In the following the true leakage reactance will be termed the leakage reactance and the mutual leakage reactance will be called the mutual reactance.

The relative magnitude of the leakage and the mutual reactance of a winding depends upon the spacing and arrangement of the coils. If the spacing is large the mutual reactance is small and in some cases may even become negligible.

The standard short-circuit test gives the equivalent leakage impedance of any two windings of a transformer. Equation (**11**) expresses short-circuit conditions when V_2 is zero. Fig. 3 shows the vector diagram of a short-circuited transformer, the exciting current being neglected and the primary vectors being rotated

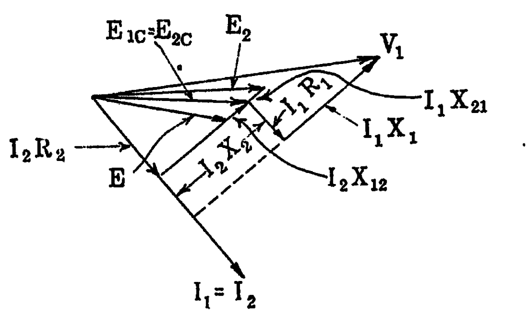

FIG. 3—VECTOR DIAGRAM OF A SHORT-CIRCUITED TRANSFORMER, SHOWING RESISTANCE, LEAKAGE REACTANCE AND MUTUAL REACTANCE DROPS

through 180 deg. Both leakage reactance drops and mutual reactance drops are indicated on the diagram.

EXPERIMENTAL DETERMINATION OF SEPARATE LEAKAGE REACTANCES

a. General. The experimental method by which the separate leakage reactance of the windings of a transformer may be determined makes use of the third harmonic component which inherently exists in the magnetizing current of a transformer when a sinusoidal voltage is impressed. The method is applicable only when a three-phase bank of three identical transformers is available. Attempts made to determine the leakage reactance of a single transformer did not meet with success.

The principle of the method is as follows: If sinusoidal voltages are impressed on a Y-Δ-connected bank of transformers, the third harmonic component of the magnetizing current will be confined to the delta where it appears as a circulating current. If the transformers are perfectly balanced and there is no external load on the secondary, no current other than the third harmonic and its multiples can exist in the delta. Usually the ninth and fifteenth harmonics, etc., are negligible and need not be considered. The third harmonic electromotive force induced per phase of the delta is just balanced by the triple frequency impedance drop due to the circulatory third harmonic current. The problem is then to measure with precision the proper third harmonic electromotive force and current, which, by simple division, will give the desired triple frequency leakage impedance.

b. Two-winding Transformers. The bank is connected Y-Δ and balanced sinusoidal voltages impressed. The third harmonic current in the delta and the third harmonic electromotive force per phase on the primary side are recorded. The latter is most practically obtained by connecting a Y-connected resistor bank between the lines and measuring the voltage between the resistor and transformer neutrals.

If the generator is Y-connected and its phase voltage is free from a third harmonic (and multiples), the bank of resistors may be omitted and the voltage measured between generator and transformer neutrals. No commercial Y-connected generator, however, is entirely without a third harmonic component in its voltage to neutral, so this method is scarcely of practical interest.

As a rule, it will be necessary to take oscillographic records and take out the third harmonics by analysis. While the current in the delta is sensibly third harmonic, a fundamental and also other harmonics are unavoidable between the two neutrals if even the slightest unbalance in the impressed voltages, the resistors or the transformers themselves is present.

The diagram of connections and the third harmonic vector diagram are given in Fig. 4 and Fig. 5, respectively. One to one ratio of transformation is assumed.

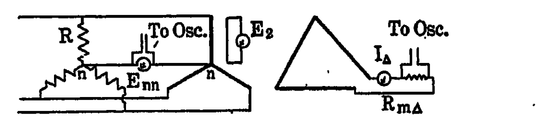

FIG. 4—DIAGRAM OF CONNECTIONS FOR LEAKAGE IMPEDANCE TEST ON TWO-WINDING TRANSFORMER

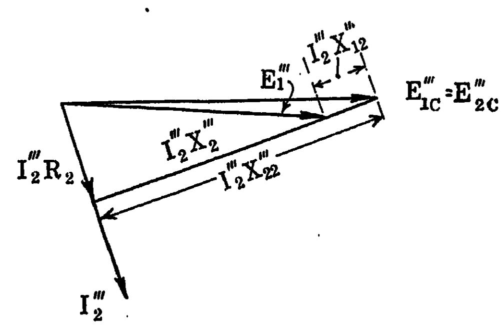

FIG. 5—VECTOR DIAGRAM OF THIRD HARMONIC QUANTITIES INVOLVED IN THE "TWO-WINDING METHOD"

If the transformers have another ratio, the quantities in the various equations given below should all be referred to the same side.

If R is the resistance of the resistors per phase, r the resistance of the voltmeter, and E_{nn}''' the third harmonic voltage between the neutrals, then

$$E_1''' = E_{nn}''' \left(1 + \frac{R}{3\,r}\right) \qquad (12)$$

This voltage is the vector sum of two components. One component (E_{c1}''') is induced in each primary winding by the triple frequency flux (ϕ_c''') in the core.

The second component ($-jX_{12}'''I_2'''$) is induced by the part of the third harmonic flux in the air which produces linkages with the primary winding. Hence from equation (**10**), considering voltage rises,

$$E_1''' = E_{1c}''' - jX_{12}'''I_2''' = E_{2c}''' - jX_{12}'''I_2''' \quad (13)$$

The triple frequency leakage impedance and reactance of the secondary windings are now found by

$$Z_2''' = \frac{E_1'''}{I_2'''} \quad (14)$$

$$X_2''' = \sqrt{(Z_2''')^2 - (R_2)^2} \quad (15)$$

This X_2''' is a *true triple frequency leakage reactance.* By repeating the measurements with the original primary winding as secondary and vice versa, the leakage reactance of the other winding may be found in a similar manner. Dividing the triple frequency reactances by three, the fundamental reactances are found.

Having determined the individual leakage reactances, the equivalent impedance of the transformer becomes (1 to 1 ratio assumed):

$$Z_e' = \sqrt{(R_1 + R_2)^2 + (X_1' + X_2')^2} \quad (16)$$

This value should, if correct, check the short-circuit impedance of the transformer to at least engineering accuracy.

c. Three-winding Transformers. When the transformers have more than two windings, a more convenient method may be used which eliminates the necessity of establishing the artificial neutral on the primary side. As before, the primaries are Y-connected, while the other two windings are Δ-connected. One delta is closed and the circulating third harmonic current in it recorded. The other delta is not closed; the third harmonic voltage appearing across the open corner of this delta may therefore be measured and will for balanced conditions be equal to three times the third harmonic electromotive force per phase. Recording these two quantities makes it possible to determine the leakage reactance of the closed delta winding with respect to the open delta winding. In many cases oscillographic records are unnecessary when the transformers are well balanced, as both the voltage and the current will be sensibly third harmonic.

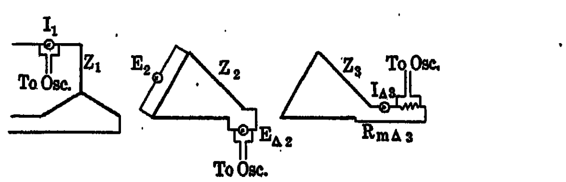

FIG. 6—DIAGRAM OF CONNECTIONS FOR LEAKAGE IMPEDANCE TEST ON THREE-WINDING TRANSFORMER

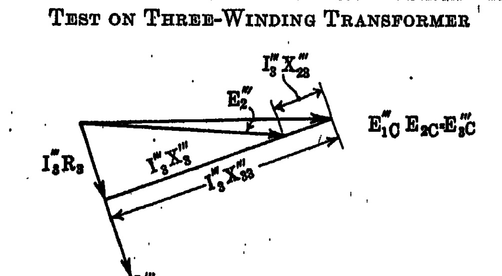

FIG. 7—VECTOR DIAGRAM OF THIRD HARMONIC QUANTITIES INVOLVED IN THE "THREE-WINDING METHOD"

The connections are shown in Fig. 6 and the third harmonic vector diagram in Fig. 7.

Solution of the vector diagram exactly as in the preceding case gives the leakage reactance of winding No. 3 with respect to winding No. 2. By repeating the measurements with changed connections, the other individual reactances are obtained.

It is beyond the scope of this paper to discuss how the separate leakage impedances in a three-winding transformer may be combined for the purpose of calculating load division, etc., between the various windings when they all carry currents.

EXPERIMENTAL WORK

a. Apparatus. Fig. 8 shows one of the test transformers used for the experimental work in the Electrical Research Laboratories of the Massachusetts Institute of Technology. Three transformers of this type were used, the approximate rating of each being two kw.

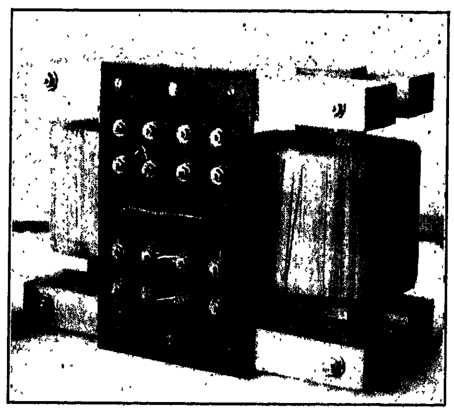

FIG. 8—CORE-TYPE EXPERIMENTAL TRANSFORMER USED IN THE TESTS AT THE MASSACHUSETTS INSTITUTE OF TECHNOLOGY

The cores, built up of silicon steel laminations with lap joints, are firmly held together by wooden frames with through-going brass bolts. The dimensions of each lamination are 8 in. by 1½ in. by 0.014 in. The gross thickness of the cores is 2 in., giving a gross cross-sectional area of 3 sq. in. (19.36 sq. cm.). Assuming 95 per cent lamination factor, the net area becomes 2.85 sq. in. (18.4 sq. cm.).

There are four coils on each leg, numbered 1, 2, 3, and 4, in the order of their proximity to the core. Each coil consists of 100 turns, double cotton covered copper wire, wound in two layers with the thickness of the insulation only between layers. Coils No. 1 and No. 2 are wound with No. 12 B. & S. wire and are separated by the thickness of the insulation only. Coil No. 3, also of No. 12 wire, is spaced ¾ in. from coil No. 2, beind supported by square wooden spacers. Coil No. 3 has wound with it a search coil of No. 24 wire, which is designated as coil No. 4.

Both ends of each coil are brought out to binding posts on a fibre terminal board. During most of the tests the corresponding coils on the two legs were connected in series, forming windings of 200 turns.

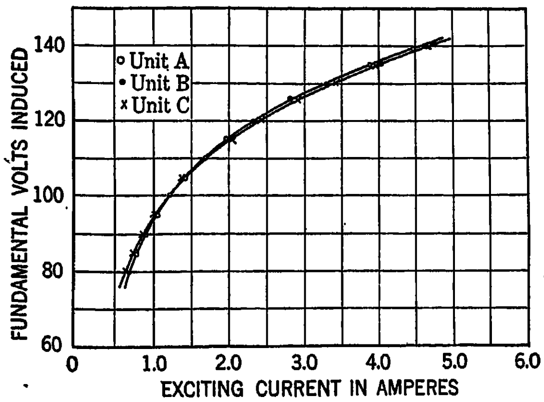

FIG. 9—SINGLE-PHASE EXCITING CURRENT OF THE EXPERIMENTAL TRANSFORMERS. THE CURVES SHOW THAT THE TRANSFORMERS WERE WELL BALANCED ELECTRICALLY

The transformers were well balanced electrically. This is apparent from Fig. 9, which shows curves of the exciting currents of the three units as obtained from single-phase tests with a sinusoidal voltage impressed.

As source of power a three-phase, 60-cycle, 5-kw., 230-115-volt sine-wave generator was used. This generator gave a very staisfactory wave shape at all balanced loads.

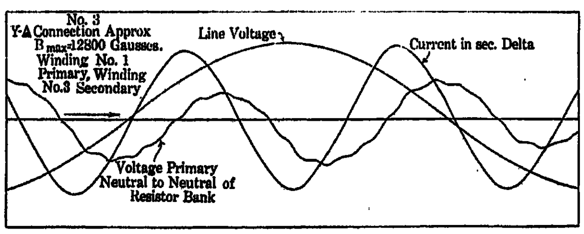

FIG. 10—OSCILLOGRAM FROM LEAKAGE IMPEDANCE TEST ON TWO-WINDING TRANSFORMER. CIRCUIT CONNECTIONS SHOWN IN FIG. 4.

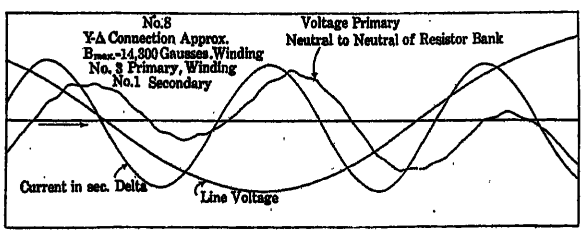

FIG. 11—OSCILLOGRAM FROM LEAKAGE IMPEDANCE TEST ON TWO-WINDING TRANSFORMER. CIRCUIT CONNECTIONS SHOWN IN FIG. 4

Vacuum thermocouples were used for the measurements whenever it was necessary to record voltages without drawing appreciable current, and also in order to measure currents in circuits where commercial ammeters would cause serious disturbance in existing conditions. Either shunt or series resistance was used in the heater circuit in order to adapt the thermocouple to any desired range. A microammeter was used as indicator in the circuit of the thermo-element.

b. Test Results.[5] Figs. 10 and 11 show two of a series of oscillograms when the "two-winding" test was applied to the experimental transformers. Fig. 10 was taken while the winding designated No. 1 was used as primary, winding No. 3 being secondary. In Fig. 11, winding No. 3 was primary, No. 1 secondary. The spacing between these two windings is large enough so as to make the mutual effect of the air fluxes small.

The necessity of using oscillographic records when this connection with artificial neutral on the primary side is used is best illustrated by the curves (Fig. 12) which give the triple frequency leakage impedance of coil No. 1 and coil No. 3 as computed directly from meter readings. According to these curves the leakage

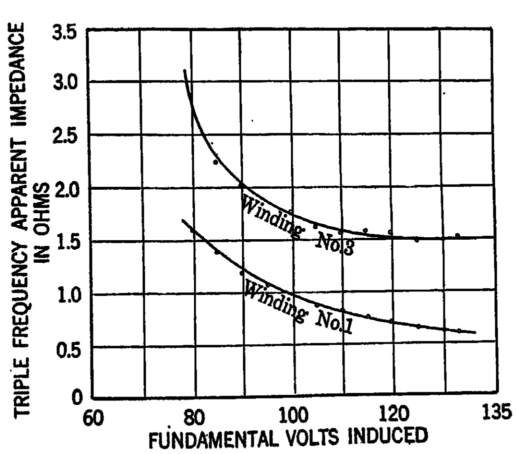

FIG. 12—THE CURVES SHOW THE "APPARENT" LEAKAGE IMPEDANCE AS OBTAINED FROM METER READINGS ALONE USING THE CONNECTIONS SHOWN IN FIG. 4. THE "APPARENT" VARIATION WITH SATURATION IS MAINLY DUE TO A PRONOUNCED FUNDAMENTAL VOLTAGE OF VARYING MAGNITUDE IN ADDITION TO THE THIRD HARMONIC BETWEEN THE TRANSFORMER AND RESISTOR NEUTRALS. HENCE IT IS IN GENERAL NECESSARY TO TAKE OSCILLOGRAPHIC RECORDS WHEN ARTIFICIAL PRIMARY NEUTRAL IS USED.

impedances apparently vary with the saturation, which in reality is not the case. The apparent variation is mainly due to a pronounced fundamental voltage of varying magnitude in addition to the third harmonic between the transformer and resistor neutrals (see Figs. 10 and 11).

Tables I and II give the data and results from this test performed at four values of flux density. The oscillograms were analyzed for their third harmonic components, the current waves by the 5-ordinate, and the voltage by the 11-ordinate schedule method. It will be noticed, however, that the current, without appreciable error, might have been taken directly from the meter readings since it appears to be practically

5. Part of the given experimental data were recorded by W. J. Miller, formerly of the Massachusetts Institute of Technology.

third harmonic. Inspection shows that the maximum difference between any single value of the third harmonic leakage reactance and the average is about 10 per cent.

The leakage reactance of winding No. 3 was also found by the "three-winding method." Fig. 13 shows

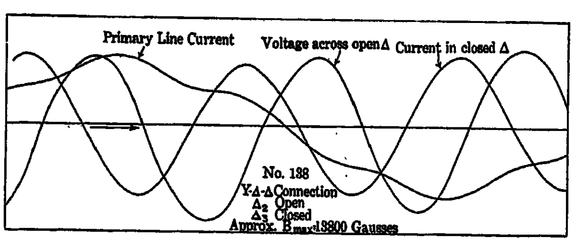

FIG. 13—OSCILLOGRAM FROM LEAKAGE IMPEDANCE ON THREE-WINDING TRANSFORMER. CIRCUIT CONNECTIONS SHOWN IN FIG. 6.

one of the oscillograms, while Table III gives the data and results from this test, which also was performed at four densities. It will be noted that the test gives the leakage reactance of winding No. 3 with respect to winding No. 2. Windings No. 1 and No. 2, however, were so close together that the leakage between them was entirely negligible; hence the leakage reactance of winding No. 3, with respect to winding No. 2, coincides with the leakage reactance of winding No. 3 with respect to winding No. 1.

As seen from the oscillogram, the current in delta No. 3 is practically a pure third harmonic, while the voltage across the open corner of delta No. 2 is very nearly third harmonic. It appears from Table III that the discrepancy between results obtained from wave analyses and those obtained directly from meter readings is only about 3½ per cent.

It will also be noted that this method gives much more consistent results than the Y-Δ method with artificial neutral point on the primary side. The four values of the leakage impedance are practically coinciding.

The value of the triple frequency leakage reactance of winding No. 3 from this test, is 1.336 ohms as compared with 1.275 ohms from the other test. The difference between the two is about 4½ per cent.

Since more consistent results are obtained in this test, the larger value of X_3''' is assumed to be the better one. Using then

$$X_1''' = 0.414 \text{ ohm}$$
$$X_3''' = 1.336 \text{ ohms}$$

the fundamental reactances become

$$X_1' = 0.138 \text{ ohm}$$
$$X_3' = 0.445 \text{ ohm}$$

The average short-circuited impedance of windings No. 1 and No. 3 obtained from a series of short-circuit tests on all transformers is 1.023 ohms, and the ohmic resistances, measured directly after the short-circuit tests, are 0.308 ohm and 0.513 ohm for windings No. 1 and No. 3 respectively. It will be noticed that these resistances are slightly larger than those used in the tables. This, of course, is due to the fact that the transformers became heated during the short-circuit tests, while the current during the other tests was entirely too small to cause any appreciable temperature rise.

Using the individual reactances in connection with the hot resistances gives for the equivalent impedance:

$$Z_e' = \sqrt{(0.308+0.513)^2 + (0.138 + 0.445)^2} = 1.007 \text{ ohm}$$

TABLE III

Connections	Oscillogram Number	Approx. flux density Gausses	Volts induced in winding No. 2 E_2	Volts across open delta $E_{\Delta 2}$	Amperes in closed delta $I_{\Delta 3}$	Ohms impedance $\frac{E_{\Delta 2}}{3\, I_{\Delta 3}}$	Ohms resistance in metering circuit $R_{m \Delta 3}$	Third harmonic volts across open delta $E_{\Delta 2}'''$	Third harmonic amperes in closed delta $I_{\Delta 3}'''$	Ohms impedance $\frac{E_{\Delta 2}'''}{3\, I_{\Delta 3}'''}$
Winding No. 1 primary Y, No. 2 open Δ, No. 3 closed Δ.	137	13100	128.0	6.10	1.310	1.552	0.66	5.88	1.308	1.500

	140	11300	111.0	3.22	0.691	1.554	0.66	3.10	0.689	1.500

Average $\frac{E_{\Delta_2}}{3\, I_{\Delta_3}} = 1.553$ ohms Average $\frac{E_{\Delta_2}'''}{3\, I_{\Delta_3}'''} = 1.501$ ohms Discrepancy = 3.46 per cent.

Average $X_3''' = \sqrt{(1.501)^2 - (0.466 + 0.66)^2} = 1.336$ ohms

The discrepancy between the two equivalent impedances is

$$\frac{1.023 - 1.007}{1.023}\, 100 = 1.56 \text{ per cent}$$

Summary

The paper has presented a method for experimental determination of separate leakage reactances of transformer windings. It is applicable only to three-phase banks of identical transformers and is based on simultaneous measurements of a third harmonic current and the third harmonic electromotive force producing it.

The method can be used both with two-winding and multi-winding transformers. It is particularly convenient, however, when the transformers have more than two windings since the necessity of establishing an artificial neutral point on the primary side is eliminated. Furthermore, oscillographic records are less important in this case due to the fact that the quantities measured are very nearly of triple frequency when the transformers are well balanced. Meter readings alone will therefore often be sufficient.

The experimental data from the tests in the Electrical Research Laboratories of the Massachusetts Institute of Technology, which have been reproduced, show that the obtained results are consistent and accurate enough for engineering purposes. This was also substantiated by the field tests previously referred to on the bank of three 2100-kv-a., 110,000/22,000/2300-volt transformers.

List of Symbols

V = Terminal voltage
E = Induced voltage
E_c = Voltage induced by flux in the core
E_Δ = Voltage across the corner of an open delta winding
I = Current
I_Δ = Circulatory current in a closed delta winding
ϕ_c = Flux exclusively confined to the core
$R_{m\Delta}$ = resistance in the corner of a closed delta winding

Subscripts attached to the above symbols refer the quantities to the particular winding designated by the subscript.

E_{nn} = Voltage between resistor and transformer neutrals
R = Resistance of resistors per phase
r = Resistance of voltmeter
R_1, R_2 = Resistance of windings No. 1 and No. 2
L_1, L_2 = Self-inductance of windings No. 1 and No. 2
$M_{12} = M_{21}$ = Mutual inductance between windings No. 1 and No. 2
M_c = Mutual inductance due to flux in the core
X_{11}, X_{22} = Self-reactance of windings No. 1 and No. 2
$X_{12} = X_{21}$ = Mutual reactance of windings No. 1 and No. 2
X_1, X_2 = Leakage reactance of windings No. 1 and No. 2 with respect to some specified winding
R_e = Equivalent resistance of two windings
X_e = Equivalent reactance of two windings
$\omega = 2\pi f$ = Angular velocity

Several of the above quantities are different for the various harmonics. Primes attached to these quantities indicate the order of the harmonic.

Discussion

For discussion of this paper see page 810.

Transformer Harmonics and Their Distribution

BY O. G. C. DAHL*

Associate, A. I. E. E.

Synopsis.—This paper discusses briefly the distribution of harmonics in single-phase transformers and in three-phase banks of single-phase transformers. Two-winding transformers or three-winding transformers, where the harmonic current exists in two of the windings only, are considered.

Formulas for the distribution of harmonic currents between primary and secondary circuits are given.

Data and results from tests on small experimental transformers in the Research Laboratories of the Electrical Engineering Department, Massachusetts Institute of Technology, and also from field tests on a bank of power transformers and a transmission line, have been reproduced.

Both in laboratory and field tests calculated and measured values check to engineering accuracy.

INTRODUCTION

DURING the last few years an investigation of the general subject of transformer harmonics has been undertaken by the Research Division of the Electrical Engineering Department, Massachusetts Institute of Technology. In a concurrent paper, the writer, who has been intimately associated with the various phases of this research, has discussed a method for experimental determination of the separate leakage reactances of transformer windings.

The purpose of this paper is to give a brief discussion of the problem of transformer harmonics and their distribution between primary and secondary circuits. Some data from laboratory tests on small experimental transformers and also some data and results from tests on a bank of three 2100-kv-a., 110,000/22,000/2300-volt transformers are presented.

SINGLE-PHASE TRANSFORMERS

It is a well-known fact that when a sinuoidal voltage is impressed upon a single-phase transformer the exciting current that it takes will be non-sinusoidal. The number and magnitude of the harmonics which the exciting current contains depend upon the characteristics of the iron and the maximum density at which it is operated.

The third harmonic is generally by far the most prominent, while usually an appreciable fifth also is present. Higher odd harmonics are also easily traced, but their magnitude is, in general, very small. These higher harmonics are, therefore, of minor importance as far as the operation of the transformer is concerned. At normal saturation the fundamental is about 90 per cent, the third harmonic about 45 per cent, and the fifth harmonic about 15 per cent of the equivalent sinusoidal exciting current. The percentage harmonics increase with the flux density as long as this is not forced up to abnormal values. At such abnormal saturations the percentage harmonics may be expected to decrease.

In the discussion of distribution of harmonics which follows, the third harmonic alone is mentioned and the equations have been established for this harmonic. It should be noted, however, that in single-phase connections all harmonics follow the same laws and what is said in regard to the third harmonic will hold for any harmonic.

Consider the third harmonic components in the transformer circuit shown in Fig. 1. In general, third harmonic currents will flow in the secondary as well as in the primary circuit.

The voltage of the generator is assumed to be strictly sinusoidal. Since third harmonic currents exist they must be produced by triple frequency electromotive forces. Being sinusoidal, the impressed voltage cannot directly give rise to third harmonic currents. Hence the triple frequency electromotive forces are generated by a triple frequency flux in the iron core. Assuming unity ratio of transformation, or referring all quantities to the same side, the third harmonic electromotive

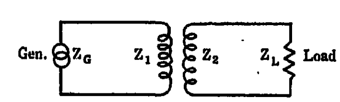

FIG. 1—LOADED SINGLE-PHASE TRANSFORMER

forces induced in the two windings by this flux are equal in magnitude and phase. The following equations inter-relate the third harmonic quantities:

$$V_1''' = I_1''' Z_G''' = E_{1C}''' - I_1''' Z_{11}''' - j X_{12}''' I_2''' \quad (1)$$

$$V_2''' = I_2''' Z_L''' = E_{2C}''' - I_2''' Z_{22}''' - j X_{21}''' I_1''' \quad (2)$$

$$Z_{11}''' = R_1 + j (X_1''' + X_{12}''') \quad (3)$$

$$Z_{22}''' = R_2 + j (X_2''' + X_{21}''') \quad (4)$$

The symbols used in these equations have the following meaning:

$E_{1C}''' = E_{2C}'''$ = third harmonic electromotive forces induced in the windings by the flux in the core

$V_1''', \ V_2'''$ = third harmonic terminal voltages

$I_1''', \ I_2'''$ = third harmonic currents

$Z_{11}''', \ Z_{22}'''$ = third harmonic self-impedances

$Z_1''', \ Z_2'''$ = third harmonic leakage impedances

X_{12}''', X_{21}''' = third harmonic mutual reactances

Z_G''' = third harmonic impedance of generator and primary leads

Z_L''' = third harmonic impedance of load and secondary leads

*Massachusetts Institute of Technology.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

It is apparent that it is impossible to get entirely rid of a small third harmonic component in the terminal voltages of a transformer, even if the generator voltage is a pure sine wave. The complete elimination of the third harmonic voltage components would require zero triple frequency impedance of the circuits (or one of the circuits) where the third harmonic current flows, a condition which of course never can be fulfilled.

In single-phase or polyphase connections, however, where no appreciable impedance is offered to the flow of the third harmonic current, the triple frequency voltages will usually be so small as to be entirely negligible in comparison with the fundamental component. The resultant voltages, therefore, will be sensibly sinusoidal.

Not only the magnitude, but also the phase of the impedance which the third harmonic current must overcome, has an important effect on the magnitude of the third harmonic voltages and currents. Without going into the question in further detail it may be said that a lagging third harmonic current in general reduces the triple frequency flux in the core, while a leading current tends to amplify it. The author intends to discuss the mechanism of this interaction in a future paper.

Transposing terms, equations (1) and (2) may be written:

$$E_{1C}''' = I_1''' (Z_{11}''' + Z_G''') + j\, I_2''' X_{12}''' \qquad (5)$$

$$E_{2C}''' = I_2''' (Z_{22}''' + Z_L''') + j\, I_1''' X_{21}''' \qquad (6)$$

By equating these expressions the distribution of the third harmonic current between the primary and secondary is obtained. The ratio of the currents is:

$$\frac{I_1'''}{I_2'''} = \frac{Z_{22}''' + Z_L''' - j\, X_{12}'''}{Z_{11}''' + Z_G''' - j\, X_{21}'''} = \frac{Z_2''' + Z_L'''}{Z_1''' + Z_G'''} \qquad (7)$$

Equation (7) shows that the distribution of third harmonic current between the two windings depends upon the leakage impedance of the windings and upon the external impedances. The distribution is inversely proportional to the ratio of the total impedances of the two circuits.

Usually the load impedance will be very much greater than the other impedances involved (the two leakage impedances and the generator impedance) when referred to the secondary side. Hence, in general, the third harmonic current in the primary will be many times greater than in the secondary when both currents are referred to the same side. If they are not referred to the same side, the actual third harmonic current in the primary may of course be the smaller in the case of a step-down transformer of large ratio.

It may be said, then, that the distribution of third harmonic current between the two windings of a transformer is largely regulated by the magnitude and character of the triple frequency impedance of the load. The minimum fundamental impedance of the load is determined by the rating of the transformer. The load, however, may easily be made large to the fundamental and still extremely small to the third harmonic by a suitable combination of inductance and capacitance in series. Let

$$Z_2''' + Z_L''' = R_2 + j\, X_2 + R_L + j\, (X_L''' - X_C) \qquad (8)$$

If then

$$X_2''' + X_L''' - X_C''' = 0 \qquad (9)$$

the secondary is tuned to series resonance for the third harmonic current. If at the same time the load resistance is zero, the ratio of the secondary third harmonic current to the primary third harmonic current is a maximum, the distribution being given by

$$\frac{I_1'''}{I_2'''} = \frac{R_2}{Z_1''' + Z_G'''} \qquad (10)$$

It should not be inferred from this statement that the secondary "leakage resonance" condition gives rise to the maximum amount of third harmonic current. Much larger currents as well as voltages may be obtained at other capacitive loads and at a second resonance condition. Operation in this region is also at certain points accompanied by peculiar instability phenomena, the discussion of which is beyond the scope of this paper.*

There has been considerable discussion of the causes for the harmonics in the magnetizing current and the voltage of a transformer. While opinions on this question have differed a good deal in earlier years, most engineers now agree they are caused both by the varying permeability of the iron and by hysteresis.†

The relation of the harmonics to the power losses in the core, however, has not, as far as the writer is aware, been settled to everybody's satisfaction.‡ The writer's conception of this question is outlined in the following.

If the voltage of the generator is strictly sinusoidal, then none of the harmonic currents can produce power in conjunction with this voltage. Hence, power is input to the core at fundamental frequency only.

The harmonic currents, however, will necessarily give rise to a copper loss in the circuits where they exist. The power corresponding to this copper loss, plus the losses in the core caused by the non-fundamental fluxes, is then evidently conveyed to the core as power of fundamental frequency. In the core, it is converted to power of other frequencies, a part of which is given out to the circuits where the currents of the higher frequencies flow.

The transformer core is in this respect nothing but a frequency converter, and the harmonics add to what

*These instability effects have been and are still being investigated in the Electrical Research Laboratories of the Massachusetts Institute of Technology.

†Excellently discussed by J. J. Frank, Bibliography 20.

‡The reading of some of the papers and the discussions given in the bibliography will show this.

may be called the "apparent core loss," or to the fundamental input to the core, while in reality a part of this power is expended as copper loss by harmonic currents.

Conceive a hypothetical transformer having core loss but requiring no harmonics in the magnetizing current for impressed sinusoidal voltage. The vector diagram on open circuit is given in Fig. 2, and the exciting current taken is I_n'. The hypothetical core is now exchanged for a regular iron core requiring harmonics in the magnetizing current. Fig. 2 may now be used as a vector diagram of fundamental quantities only. Neglecting the slight change in the fundamental leakage impedance drop of the primary, the only effect of the sudden introduction of harmonics in the current would be to increase the excitation conductance of the transformer. It would now draw a fundamental current I_n and the apparent increase in core loss is:

$$E_1\,(I_c - I_c')\text{ watts} \qquad (11)$$

This power is, as already pointed out, not utilized as power of fundamental frequency but is converted to power of higher frequencies, part of which is absorbed by the core (and this part may be very small if the non-fundamental fluxes are small), while the rest is

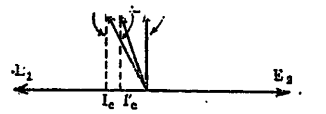

FIG. 2—VECTOR DIAGRAM SHOWING INCREASE IN "APPARENT CORE LOSS"

dissipated as copper loss in the circuits carrying the harmonic currents.

THREE-PHASE CONNECTIONS OF SINGLE-PHASE TRANSFORMERS

When single-phase transformers are connected for three-phase operation, the method of connection constitutes a means by which the distribution of the third harmonics and multiples may be partly controlled independent of the external circuits. This depends upon the well-known fact that the triple frequency voltages and currents in a balanced system are in phase in the three phases; in other words they appear as residuals.

The third harmonic voltage, therefore, cannot appear between lines while it may be found as a component of the voltage to neutral. The third harmonic current can appear on the lines only in a Y-connection with neutral. In a Δ-connection it will circulate in the closed delta but cannot escape from this and enter the lines.

The other harmonics which are not multiples of three and hence are phase-displaced 120 deg. in the three phases, cannot be controlled by transformer connections independent of the external circuits.

In the following discussion of the distribution of the harmonics strictly sinusoidal impressed voltages and balanced transformers are assumed. The ratio of transformation of the transformers is assumed to be unity.

Since the same laws do not govern the distribution of the two classes of harmonics, *i. e.*, the third harmonic and its multiples and those which are not multiples of three, equations for the fifth as well as for the third harmonics have been established. The generator and the balanced load are both assumed Y-connected for all transformer connections. The equations given, however, are easily modified to hold when either generator or load, or both, are delta-connected. "No load" in all cases means that the secondary lines are opened at the transformer terminals.

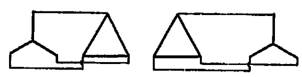

FIG. 3

It should be noted that voltages and currents of triple frequency are given *per transformer*. In a Y-connection this is equivalent to *voltage to neutral* and *line current*. Fifth harmonic voltages and currents are to neutral and per line, respectively, for any connection used.

This significance of the symbols used in the equations below should be kept in mind, as otherwise the equations are easily open to incorrect interpretation.

A. Δ–Δ CONNECTION

With this connection (Fig. 3), the third harmonic currents cannot appear on the lines, but will exist as circulating currents in the two deltas. Conditions are the same whether the transformer bank is loaded or not.

The induced third harmonic electromotive forces are given by

$$\begin{aligned} E_{1c}''' = E_{2c}''' &= I_1'''\,Z_{11}''' + j\,I_2'''\,X_{12}''' \\ &= I_2'''\,Z_{22}''' + j\,I_1'''\,X_{21}''' \end{aligned} \qquad (12)$$

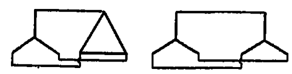

FIG. 4

and the division of third harmonic current between primary and secondary is given by

$$\frac{I_1'''}{I_2'''} = \frac{Z_2'''}{Z_1'''} \qquad (13)$$

The fifth harmonic currents will appear on the lines. When the transformers are loaded the following equations hold:

$$\begin{aligned} E_{1c}^{\mathrm{v}} = E_{2c}^{\mathrm{v}} &= I_1^{\mathrm{v}}\left(\frac{Z_{11}^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) + j\,I_2^{\mathrm{v}}\,\frac{X_{12}^{\mathrm{v}}}{3} \\ &= I_2^{\mathrm{v}}\left(\frac{Z_{22}^{\mathrm{v}}}{3} + Z_L^{\mathrm{v}}\right) + j\,I_1^{\mathrm{v}}\,\frac{X_{21}^{\mathrm{v}}}{3} \end{aligned} \qquad (14)$$

$$\frac{I_1^{\mathrm{v}}}{I_2^{\mathrm{v}}} = \frac{Z_2^{\mathrm{v}} + 3\,Z_L^{\mathrm{v}}}{Z_1^{\mathrm{v}} + 3\,Z_G^{\mathrm{v}}} \qquad (15)$$

When the load is disconnected (at the secondary terminals of the bank) the fifth harmonic current ceases to flow in the secondary windings, while a fifth harmonic voltage V_2^{v} still appears on the secondary side. The following relations hold:

$$E_{1c}^{\mathrm{v}} = E_{2c}^{\mathrm{v}} = I_1^{\mathrm{v}}\left(\frac{Z_{11}^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) \tag{16}$$

$$V_2^{\mathrm{v}} = E_{2c}^{\mathrm{v}} - j\, I_1^{\mathrm{v}} \frac{X_{21}^{\mathrm{v}}}{3} = I_1^{\mathrm{v}}\left(\frac{Z_1^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) \tag{17}$$

B. Δ-Y CONNECTION

Isolated neutrals. With this connection (Fig. 4), the

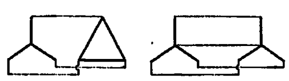

FIG. 5

third harmonic current will be confined to the primary delta both when the bank is loaded and when it is on open circuit. The following equations will hold:

$$E_{1c}''' = E_{2c}''' = I_1''' Z_{11}''' \tag{18}$$

$$V_2''' = E_{2c}''' - j\, I_1''' X_{21}''' = I_1''' Z_1''' \tag{19}$$

The equations for the fifth harmonic when the bank is loaded are

$$E_{1c}^{\mathrm{v}} = \frac{E_{2c}^{\mathrm{v}}}{\sqrt{3}} = I_1^{\mathrm{v}}\left(\frac{Z_{11}^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) + j\,\frac{I_2^{\mathrm{v}}}{\sqrt{3}}\, X_{12}^{\mathrm{v}}$$

$$= \frac{I_2^{\mathrm{v}}}{\sqrt{3}}\left(Z_{22}^{\mathrm{v}} + Z_L^{\mathrm{v}}\right) + j\, I_1^{\mathrm{v}} \frac{X_{21}^{\mathrm{v}}}{3} \tag{20}$$

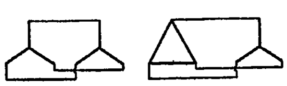

FIG. 6

$$\frac{I_1^{\mathrm{v}}}{I_2^{\mathrm{v}}} = \frac{\sqrt{3}\,(Z_2^{\mathrm{v}} + Z_L^{\mathrm{v}})}{Z_1^{\mathrm{v}} + 3\, Z_G^{\mathrm{v}}} \tag{21}$$

Disconnecting the load gives

$$E_{1c}^{\mathrm{v}} = \frac{E_{2c}^{\mathrm{v}}}{\sqrt{3}} = I_1^{\mathrm{v}}\left(\frac{Z_{11}^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) \tag{22}$$

$$V_2^{\mathrm{v}} = E_{2c}^{\mathrm{v}} - j\,\frac{I_1^{\mathrm{v}}}{\sqrt{3}}\, X_{21}^{\mathrm{v}} = \sqrt{3}\, I_1^{\mathrm{v}}\left(\frac{Z_1^{\mathrm{v}}}{3} + Z_G^{\mathrm{v}}\right) \tag{23}$$

Interconnected neutrals. When the bank is loaded (Fig. 5) the following equations hold for the third harmonic:

$$E_{1c}''' = E_{2c}''' = I_1''' Z_{11}''' + j\, I_2''' X_{12}'''$$

$$= I_2\,(Z_{22}''' + Z_L''' + 3\, Z_{2n}''') + j\, I_1''' X_{21}''' \tag{24}$$

$$\frac{I_1'''}{I_2'''} = \frac{Z_2''' + Z_L''' + 3\, Z_{2n}'''}{Z_1'''} \tag{25}$$

When the load is removed equations (18) and (19) express the triple frequency relations.

The fifth harmonic will follow the same laws as in the case with isolated neutrals and is hence determined by equations (20), (21), (22) and (23).

C. Y-Δ CONNECTION.

Isolated neutrals. With this connection (Fig. 6), the third harmonic current will be exclusively confined to

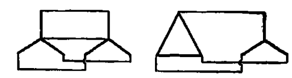

FIG. 7

the secondary delta both for load and no-load conditions. The following equations hold:

$$E_{c1}''' = E_{c2}''' = I_2''' Z_{22}''' \tag{26}$$

$$V_1''' = E_{c1}''' - j\, I_2''' X_{12}''' = I_2''' Z_2''' \tag{27}$$

When the bank is loaded the fifth harmonic relations are

$$E_{1c}^{\mathrm{v}} = \sqrt{3}\, E_{2c}^{\mathrm{v}} = I_1^{\mathrm{v}}\,(Z_{11}^{\mathrm{v}} + Z_G^{\mathrm{v}}) + j\,\frac{I_2^{\mathrm{v}}}{\sqrt{3}}\, X_{12}^{\mathrm{v}}$$

$$= \sqrt{3}\, I_2^{\mathrm{v}}\left(\frac{Z_{22}^{\mathrm{v}}}{3} + Z_L^{\mathrm{v}}\right) + j\, I_1^{\mathrm{v}} X_{21}^{\mathrm{v}} \tag{28}$$

$$\frac{I_1^{\mathrm{v}}}{I_2^{\mathrm{v}}} = \frac{Z_2^{\mathrm{v}} + 3\, Z_L^{\mathrm{v}}}{\sqrt{3}\,(Z_1^{\mathrm{v}} + Z_G^{\mathrm{v}})} \tag{29}$$

Removing the load gives

$$E_{1c}^{\mathrm{v}} = \sqrt{3}\, E_{2c}^{\mathrm{v}} = I_1^{\mathrm{v}}\,(Z_{11}^{\mathrm{v}} + Z_G^{\mathrm{v}}) \tag{30}$$

$$V_2^{\mathrm{v}} = E_{2c}^{\mathrm{v}} - j\,\frac{I_1^{\mathrm{v}}}{\sqrt{3}}\, X_{21}^{\mathrm{v}} = \frac{I_1^{\mathrm{v}}}{\sqrt{3}}\,(Z_1^{\mathrm{v}} + Z_G^{\mathrm{v}}) \tag{31}$$

Interconnected neutrals. With this connection (Fig. 7), the third harmonic current will flow in the primary lines and the secondary delta both at no-load and when the bank is loaded. The following equations hold:

$$E_{1c}''' = E_{2c}''' = I_1'''(Z_{11}''' + Z_G''' + 3\, Z_{1n}''')$$

$$+ j\, I_2''' X_{12}''' = I_2''' Z_{22}''' + j\, I_1''' X_{21}''' \tag{32}$$

$$\frac{I_1'''}{I_2'''} = \frac{Z_2'''}{Z_1''' + Z_G''' + 3\, Z_{1n}'''} \tag{33}$$

The neutral connection does not affect the fifth

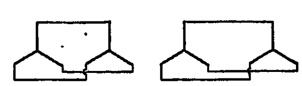

FIG. 8

harmonics; they still follow equations (28), (29), (30) and (31).

D. Y-Y CONNECTION

All neutrals Isolated. With this connection (Fig. 8), no third harmonic current can flow on either side under

any condition. A third harmonic voltage, however, which may be very large, exists on both sides.

$$V_1''' = V_2''' = E_{1C}''' = E_{2C}''' \quad (34)$$

When the bank is loaded the equations for the fifth harmonic are

$$E_{1C}^{\mathrm{v}} = E_{2C}^{\mathrm{v}} = I_1^{\mathrm{v}}(Z_{11}^{\mathrm{v}} + Z_G^{\mathrm{v}}) + j\,I_2^{\mathrm{v}} X_{12}^{\mathrm{v}}$$
$$= I_2^{\mathrm{v}}(Z_{22}^{\mathrm{v}} + Z_L^{\mathrm{v}}) + j\,I_1^{\mathrm{v}} X_{21}^{\mathrm{v}} \quad (35)$$

$$\frac{I_1^{\mathrm{v}}}{I_2^{\mathrm{v}}} = \frac{Z_2^{\mathrm{v}} + Z_L^{\mathrm{v}}}{Z_1^{\mathrm{v}} + Z_G^{\mathrm{v}}} \quad (36)$$

Disconnecting the load gives

$$E_{1C}^{\mathrm{v}} = E_{2C}^{\mathrm{v}} = I_1^{\mathrm{v}}(Z_{11}^{\mathrm{v}} + Z_G^{\mathrm{v}}) \quad (37)$$

$$V_2^{\mathrm{v}} = E_{2C}^{\mathrm{v}} - j\,I_1^{\mathrm{v}} X_2^{\mathrm{v}} = I_1^{\mathrm{v}}(Z_1^{\mathrm{v}} + Z_G^{\mathrm{v}}) \quad (38)$$

Primary and generator neutrals interconnected. With this connection (Fig. 9), the third harmonic current

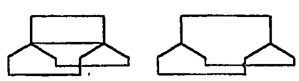

FIG. 9

will flow on the primary side both at no-load and when load is put on the bank. The equations for the third harmonics are

$$E_{1C}''' = E_{2C}''' = I_1'''(Z_{11}''' + Z_G''' + 3\,Z_{1n}''') \quad (39)$$

$$V_2''' = E_{2C}''' - j\,I_1''' X_{21}'''$$
$$= I_1'''(Z_1''' + Z_G''' + 3\,Z_{1n}''') \quad (40)$$

The conditions as far as the fifth harmonics are concerned are identical with those existing when all

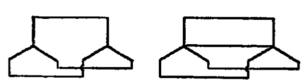

FIG. 10

neutrals are isolated as expressed by equations (35), (36), (37), and (38).

Secondary and load neutrals interconnected. When the bank is loaded, (Fig. 10), the third harmonic current will flow on the secondary side.

$$E_{1C}''' = E_{2C}''' = I_2'''(Z_{22}''' + Z_L''' + 3\,Z_{2n}''') \quad (41)$$

$$V_1''' = E_{1C}''' - j\,I_2''' X_{12}'''$$
$$= I_2'''(Z_2''' + Z_L''' + 3\,Z_{2n}''') \quad (42)$$

At no-load there is no circuit in which the third harmonic current can flow. Equation (34) holds for the voltages.

The fifth harmonics behave as in the other Y–Y connections. Equations (35), (36), (37) and (38).

Neutrals interconnected on both sides. With this connection, (Fig. 11), a third harmonic current will flow on both sides when the bank is loaded.

$$E_{1C}''' = E_{2C}''' = I_1'''(Z_{11}''' + Z_G''' + 3\,Z_{1n}''') + j\,I_2''' X_{12}'''$$
$$= I_2'''(Z_{22}''' + Z_L''' + 3\,Z_{2n}''') + j\,I_1''' X_{21}''' \quad (43)$$

$$\frac{I_1'''}{I_2'''} = \frac{Z_2''' + Z_L''' + 3\,Z_{2n}'''}{Z_1''' + Z_G''' + 3\,Z_{1n}'''} \quad (44)$$

When the load is removed, Equations (39) and (40) will evidently hold. The fifth harmonics follow Equations (35), (36), (37) and (38).

E. Y–Y CONNECTION WITH TERTIARY DELTA

Neutrals isolated. With this connection, (Fig. 12), the third harmonic current will always be confined to

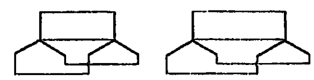

FIG. 11

the tertiary delta independent of whether the bank is loaded or not. No harmonic, other than the third and its multiples, can flow in the tertiary winding.

Designating the tertiary winding as winding No. 3 and assuming unity ratio of transformation also for this winding, the following equations may be written:

$$E_{1C}''' = E_{2C}''' = E_{3C}''' = I_3''' Z_{33}''' \quad (45)$$

$$V_1''' = E_{1C}''' - j\,I_3''' X_{13}''' = I_3''' Z_{3A}''' \quad (46)$$

$$V_2''' = E_{2C}''' - j\,X_3''' X_{23}''' = I_3''' Z_{3B}''' \quad (47)$$

In equations (46) and (47) Z_{3A}''' and Z_{3B}''' represent the third harmonic leakage impedance with respect to windings No. 1 and No. 2 respectively.

The fifth harmonics behave as in the other Y–Y connections. Equations (35), (36), (37) and (38).

LABORATORY TESTS

The data which are reproduced below were obtained in the Electrical Research Laboratories of the Massachusetts Institute of Technology by tests on three small core type transformers.*

A. SINGLE-PHASE EXCITING CURRENT

It is important in three-phase tests that the transformers are as nearly balanced as possible. The experimental transformers were well balanced electrically. This is apparent from Fig. 13, which shows curves of the exciting currents of the three units as obtained from single-phase tests with a sinusoidal voltage impressed.

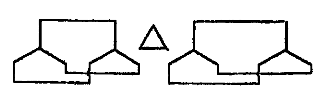

FIG. 12

Fig. 14 shows one of a series of oscillograms of the single-phase exciting current. The magnitudes of the fundamental, third harmonic and fifth harmonic components as found from analysis of this series of oscillograms are given by the curves in Fig. 15.

The curves are plotted against fundamental flux density and it will be noted that the percentage harmonics increases with the density.

*The transformers and other equipment are briefly described in the paper, "Separate Leakage Reactance of Transformer Windings."

As a typical example, the results of the analysis of the exciting-current curve in the oscillograms Fig. 14 are plotted in Fig. 16. The relative magnitudes and phase relations are correctly reproduced. The phase relation of each harmonic current, for instance the third, and the corresponding third harmonic electromotive force evidently depend on the triple frequency impedance of the circuits where it flows as established by equations (5) and (6).

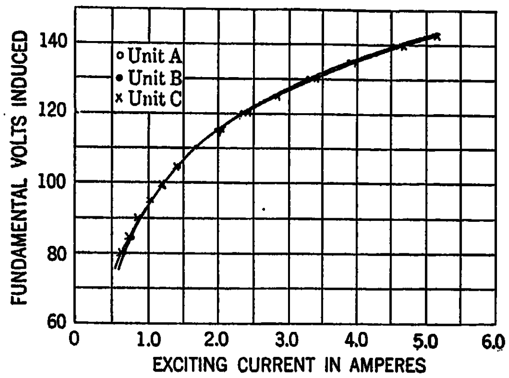

FIG. 13—EXCITING CURRENTS OF EXPERIMENTAL TRANSFORMERS SINGLE PHASE

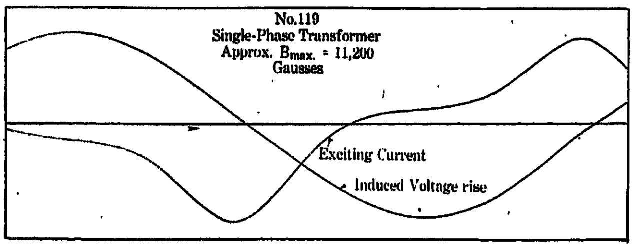

FIG. 14—OSCILLOGRAM OF SINGLE-PHASE EXCITING CURRENT

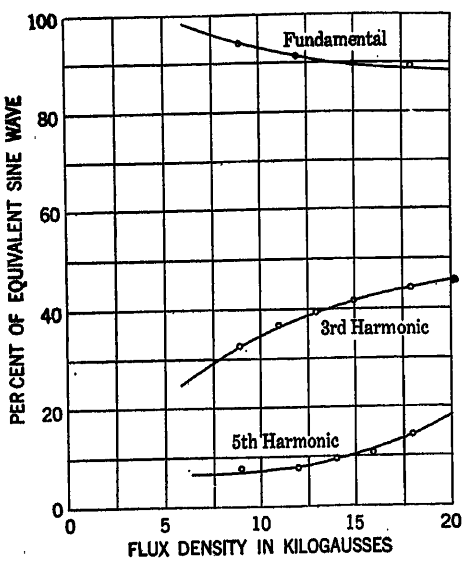

FIG. 15—COMPONENTS OF MAGNETIZING CURRENT OF EXPERIMENTAL TARNSFORMERS. SINGLE PHASE

These curves of the single-phase magnetizing current of the transformers have been included in order to give a picture of the magnetic characteristics of the transformers. The single-phase data are also interesting when compared with some of the data from three-phase tests.

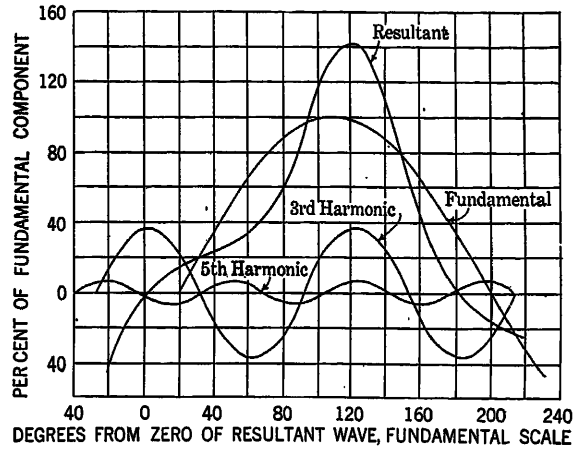

FIG. 16—COMPONENTS OF EXCITING CURRENT FROM OSCILLOGRAM FIG. 14

B. DISTRIBUTION OF THIRD HARMONICS IN THREE-PHASE BANKS

In order to investigate the distribution of third harmonic current between two circuits, a series of tests was performed with circuits of various nature provided for this current. It will be remembered from the preceding discussion that, when any harmonic electromotive force is introduced exclusively by the transformer itself, the corresponding currents set up should divide between any two circuits inversely as the ratio of their total impedances at the frequency considered.

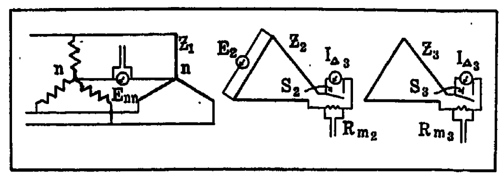

FIG. 17—DISTRIBUTION OF THIRD HARMONIC CURRENT. CIRCUIT DIAGRAM FOR Y-Δ-Δ TESTS. NO EXTERNAL LOAD

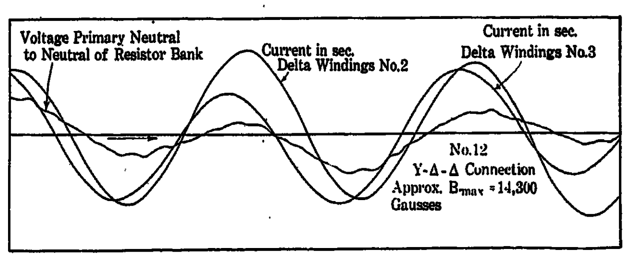

FIG. 18—DISTRIBUTION OF THIRD HARMONIC CURRENT. OSCILLOGRAM FROM *Y*-Δ-Δ TESTS. CIRCUIT CONNECTIONS SHOWN IN FIG. 17

Y–Δ–Δ *Connection.* This test was performed in order to check the theory of third harmonic current division between two closed deltas. The connections used are shown diagrammatically in Fig. 17.

Windings No. 1 were used as primaries and were Y-connected; windings No. 2 and No. 3 were used as secondaries and Δ-connected. The currents in the two deltas were recorded at five values of the flux density.

Fig. 18 shows one of the oscillograms taken during these tests. The voltage between the resistor and transformer neutrals (not necessary for this particular test) and the delta currents was recorded. The triple frequency current was separated out by analysis.

Tables I and II give the data and results from these tests. Since there was only one vacuum thermocouple ammeter suitable for measuring the current in the two deltas, it was necessary first to put the meter in delta No. 2 while the switch S_3 was closed and, after reading its deflection, to remove it and put it in delta No. 3 in order to read the current here with S_2 closed and S_3 open.

It is not possible to apply a rational correction to this current because of the change in the third harmonic electromotive force which accompanies the change in current. This change in electromotive force cannot be estimated with precision from the data at hand. The ratio of the currents would therefore be expected to be slightly too large.

Inspection of the results given in the last three columns of Table II shows this to be the case. The discrepancies, however, are not large, and bearing the above consideration in mind, the check between the measured and computed current ratios seems satisfactory.

Δ-Y connection with capacity load. These tests were made as an attempt to simulate the conditions when a Δ-Y connected transformer bank is connected to a cable or long transmission line of considerable capacity. The circuit diagram is shown in Fig. 19.

The capacities used for the tests recorded in oscillogram No. 121 and No. 123 were not quite balanced. This fact accounts for the large fundamental current in the secondary neutral. The capacities used in the other tests, however, were practically perfectly balanced and analyses show that with these capacities the third

harmonic current in the secondary neutral is by far predominant.

Fig. 20 is a sample oscillogram from this series and shows induced voltage (E_2), current in the primary delta, and current in the secondary neutral. The third harmonic current in the latter is assumed to be the algebraic sum of the third harmonic currents in each phase and equal to three times the third harmonic current per phase, two conditions which are true when perfect balance exists.

Tables III and IV give the data and results. The details of the computations are not reproduced. In obtaining the theoretical current division, the average the theoretical and measured quantities is unsatisfactory. However, a more thorough analysis of the conditions actually existing in the network during these tests permits and substantiates a much more favorable interpretation of the results.

Unfortunately, a commercial ammeter was used in the primary delta, giving a third harmonic impedance of the metering circuit in one branch of the delta of $1.14 + j\,0.665$ ohms, which is appreciable as compared with the impedance of the rest of the delta. Due to the unbalance thus introduced, the sum of the third harmonic electromotive forces will not be exactly balanced by the third harmonic impedance drop around

third harmonic impedance per phase on each side was calculated. The average primary impedance per phase is given as the impedance of one primary winding plus one third of the impedance of the metering circuit in the primary delta, *i. e.*, ammeter in series with shunt and vibrator in parallel.

In comparing the results from these tests, (Table IV), it will be noted that the observed current ratios are consistently less than the computed ratios by amounts varying from 0.48 per cent to 18.7 per cent. Since, in general, experimental errors should be divided equally between plus and minus, one may at a first glance be inclined to conclude that the check between the delta, with the result that a third harmonic current will appear on two of the lines and in two of the phases of the Y-connected generator. No third harmonic current will appear on the third line.

The third harmonic current in the two phases of the primary delta which do not contain the ammeter is equal and in phase. On the contrary, the third harmonic current in the phase where the ammeter is inserted, is neither equal to, nor in phase with, the two other currents. Since on the secondary side the third harmonic current per phase is considered equal to one third of the third harmonic current in the neutral, it is necessary for correct comparison of the third

harmonic currents on the two sides also to use the *average third harmonic current* in the primary delta, and the corresponding average triple frequency impedance per phase.

It is, therefore, evident that computing current ratios as done in Table IV, based on values of the primary third harmonic current which are smaller than the average values, discrepancies in the direction indicated might have been anticipated. Hence it seems safe to conclude that the results check to engineering accuracy.

Y–Δ connection with resonant load. Fig. 21 shows an oscillogram from a series of tests performed with the

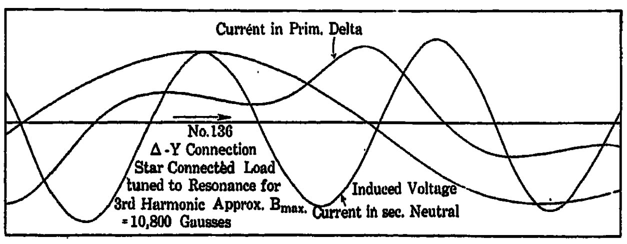

FIG. 21—DISTRIBUTION OF THIRD HARMONIC CURRENT. CIRCUIT DIAGRAM FOR Δ-*Y* TESTS. INDUCTANCE AND CAPACITY LOAD. SECONDARY CIRCUIT TUNED TO TRIPLE FREQUENCY RESONANCE

connections shown in Fig. 22, using a combined inductive and capacitive load so adjusted that the total secondary circuit was tuned to series resonance for the third harmonic.

The oscillogram shows that in this case the current in the secondary neutral, as might be expected, is practically all third harmonic, while in the test with

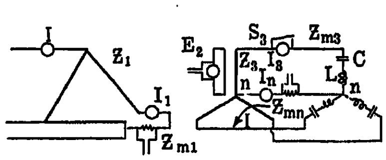

FIG. 22—OSCILLOGRAM FROM Δ-*Y* TESTS. CIRCUIT DIAGRAM SHOWN IN FIG. 21

pure capacity load this current also contained a considerable amount of higher harmonics. With the resonant circuit these are all damped out by the inductance.

The complete data from these tests will not be reproduced here as they cannot be used to verify the third harmonic current distribution. This is due to the fact that iron-core reactors (with air gaps) were used for producing resonance in the secondary circuit. Having iron cores, the reactors themselves would tend to introduce harmonics. The effect of the reactors in this respect cannot be quantitatively analyzed with sufficient precision to render the results of value for checking the theoretical distribution of third harmonic current.

FIELD TESTS

a. General. In July 1922, the Research Division of the Electrical Engineering Department, Massachusetts Institute of Technology, made a series of tests on the Gadsden-Lindale Tie Line belonging to the Alabama Power Company and the Georgia Railway and Power Company. By courtesy of these companies this line was placed at the disposal of the Institute for testing purposes. F. S. Dellenbaugh, Jr.,* was in charge of the work.

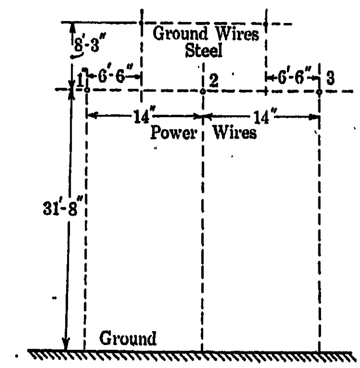

FIG. 23—CONFIGURATION OF TRANSMISSION LINE USED IN FIELD TESTS

The tests comprised mainly investigation of d-c. transients, harmonics due to transformers and determination of the separate leakage reactances of a bank

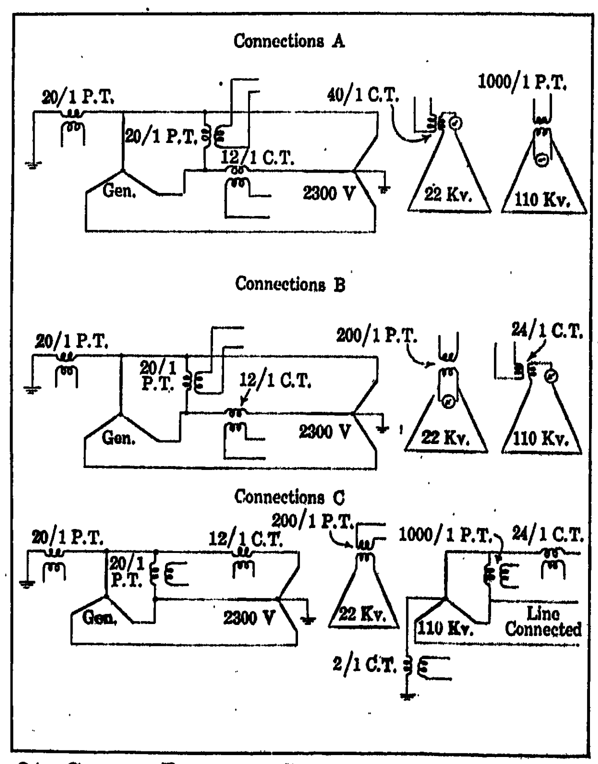

FIG. 24—CIRCUIT DIAGRAMS SHOWING CONNECTIONS USED IN FIELD TESTS

of power transformers at Gadsden. At the same time engineers of the American Telephone & Telegraph Co. made bridge measurements of the impedance to ground

*Massachusetts Institute of Technology.

†See the paper, "Separate Leakage Reactance of Transformer Windings."

of the line at frequencies from about 180 to 2400 cycles per second. Several of the tests may, therefore, be used to check some of the theory of transformer harmonics was well as the method of measurement developed in the laboratory.

Fig. 23 shows the configuration of the line from Gadsden to the State border (Alabama-Georgia). The configuration of the line from the State border to Lindale was essentially the same and will not be reproduced here. The lines were not transposed. Detailed data of the lines have no particular interest for this paper.

The transformer bank at Gadsden consisted of three 2100-kv-a. transformers made by the General Electric Company. These had three windings each and were normally connected 110,000 - 22,000 - 2300 volts in Δ - Δ - Δ.

Three series of tests are of particular value for checking the theory of transformer harmonics. Diagrams of connections used in these are shown in Fig. 24. In connections *A* and *B* will be recognized the "three-winding method"† for the determination of leakage reactances. The diagram marked "Connections *C*" shows the bank connected *Y*-open Δ-*Y* with the line connected to the 110-kv. side, the neutral being

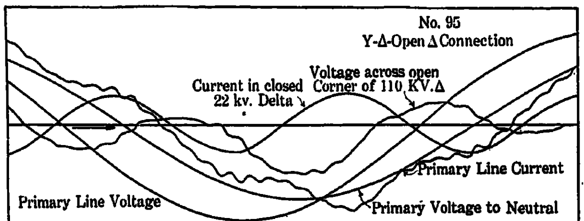

Fig. 25—Oscillogram from Leakage Impedance Tests. Circuit Connections Shown in Fig. 24-A

grounded. The distant end of the line was free. This test was also performed with the 22-kv. delta closed. As the circulating current in this delta, was not recorded, however, this test cannot be used for checking purposes.

Referring to the circuit diagrams in Fig. 24, it will be seen that primary line voltage, line current, and voltage to ground were recorded for all three connections. With connections *A* and *B*, the voltages across the open corner or the circulating currents in the deltas were read. With connection *C*, the voltage across the open corner of the 22-kv. delta and line voltage, line current and potential to ground on the *Y*-connected, 110-kv. side were recorded. All these data, however, will not be reproduced here; only those strictly required will be given, corrected for instrument transformer ratios, instrument errors, etc.

b. Separate Leakage Reactances. Fig. 25 shows one of the oscillograms taken during the tests with connections *A*. It will be seen that while the circulating current in the closed 22-kv. delta is practically a pure third harmonic, the voltage across the open corner of the 110-kv. delta contains a pronounced fundamental. This is due to unbalance of the transformers. Hence in this case it would have been impossible to rely upon meter readings alone; oscillographic records had to be used throughout the series of tests.

Table V gives the values of the voltages across the open corner of the deltas and the circulating currents necessary for determining the leakage reactances. The actual readings, the per cent third harmonic as obtained from analyses of the oscillograms, the third harmonic voltages, and currents referred to the high-tension (110,000-volt) side, and the computed leakage impedances are given.

Table VI gives the ohmic and 60-cycle effective resistances of the three windings. The separate effective resistances have been computed from the equivalent resistances as obtained from short-circuit tests, by assuming that the ratio of the separate effective resistances is equal to the ratio of the separate ohmic resistances. This assumption evidently involves a small approximation.

The 180-cycle effective resistances will be considered to be the same as at 60 cycles. The error which may result from this assumption is negligibly small, since the resistances of the windings are insignificant as compared to the reactances. Hence the third harmonic leakage impedances in Table V may be reduced to exactly 60 cycles by multiplying by the ratio of 60 and the average frequency recorded. Furthermore, the third harmonic and the fundamental (60-cycle) reactances may be found.

Table VI gives the desired values. It should be carefully noted that the leakage reactance of winding No. 2 is with respect to winding No. 3, and that of winding No. 3 with respect to winding No. 2. The leakage reactance of these windings with respect to winding No. 1 will in all probability be different from the leakage reactances given. This, however, is entirely dependent upon the arrangement and the spacing of the coils in the transformers.

c. Third Harmonic Current Distribution with Line Connected to Transformer Bank. Data from two tests performed with "Connections *C*", Fig. 24, will be checked. The third harmonic current in the neutral on the line side will be computed from the voltage across the open corner of the 22-kv. delta, the separate leakage impedance of the 110-kv. windings, and the measured impedance to ground of the line.

In the first test (oscillogram No. 106) the part of the line from Gadsden to the State border only was used; in the second test (oscillogram No. 113), however, the entire line Gadsden-Lindale was connected to the transformers. In both cases the distant end of the line was open.

Fig. 26 shows one of the oscillograms (No. 106). While the neutral current appears to be nearly third harmonic, the main part of the voltage across the open corner of the 22-kv. is delta fundamental. This is partly due to unbalance of the transformers themselves and

partly due to unbalance of the line admittances. Table VII gives the recorded data. From a set of

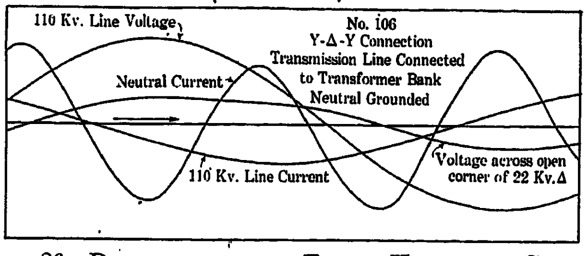

FIG. 26—DISTRIBUTION OF THIRD HARMONIC CURRENT. OSCILLOGRAM FROM FIELD TESTS. CIRCUIT CONNECTIONS SHOWN IN FIG. 25-C.

curves (not reproduced here) of line impedance to ground plotted versus frequency, the necessary line impedances can be found. With the distant end open and the three conductors in parallel, the following values at the triple frequency corresponding to the fundamental frequency recorded in Table VII are obtained:

Part of line	f cycles	Z ohms
Gadsden—State Border........	176.7	$18 - j\,775$
Gadsden—Lindale.............	176.1	$4 - j\,540$

The leakage impedance per phase of the 110-kv. windings is

$$Z_3''' = 26.3 + j\,649 \text{ ohms}$$

The total triple-frequency impedances of the high-

DISTRIBUTION OF THIRD HARMONIC CURRENT WITH LINE CONNECTED

Oscillogram Number	H. T. line voltage kv.	f cycles	$V_{\Delta 2}$ Reading volts	$V_{\Delta 2}$ Per cent third harmonic	I_{n3} Reading amperes	I_{n3} Per cent third harmonic	$V_{\Delta 2}'''$ volts	I_{n3}''' amperes
106	130.5	58.9	1114	12.35	0.404	97.8	137.8	0.395
113	129.9	58.7	970	7.6	0.368	90.7	73.7	0.334

tension circuit to be used in connection with the third harmonic currents in the neutral are:

Gadsen—State border:

$$Z''' = 18 - j\,775 + \frac{26.3}{3} + j\,\frac{639 \times 176.7}{3 \times 180}$$

$$= 26.8 - j\,556 = 566 \diagdown 87.°3 \text{ ohms}$$

Gadsden—Lindale:

$$Z''' = 4 - j\,540 + \frac{26.3}{3} + j\,\frac{639 \times 176.1}{3 \times 180}$$

$$= 12.8 - j\,332 = 332 \diagdown 87.°8 \text{ ohms}$$

The voltage to be used in connection with these impedances is the third harmonic voltage per phase in the 22-kv. winding referred to the 110-kv. side. The third harmonic voltage per phase is one-third of the third harmonic voltage across the open corner of the 22-kv. delta.

The above procedure is in accordance with equation (42) holding for a Y–Y connected bank with secondary neutral. This is evidently correct since the Y–Y connection and the open Δ–Y connection are essentially the same as far as the effect on the third harmonics is concerned.

In Table VIII, the third harmonic currents in the neutral are calculated and compared with the measured values. The check obtained must be considered very satisfactory, particularly when consideration is given to the fact that the tests were performed under difficult circumstances.

TABLE VIII
DISTRIBUTION OF THIRD HARMONIC CURRENT WITH LINE CONNECTED

All quantities referred to 110-kv. side

Oscillogram Number	f cycles	E_3''' volts	Z''' ohms	Calculated I_{n3}''' amperes	Measured I_{n3}''' amperes	Discrepancy per cent
106	58.9	229.7	566	0.405	0.395	2.53
113	58.7	122.9	332	0.370	0.334	10.8

In the tests previously referred to, where the 22-kv. delta was closed, the triple frequency component of the neutral current on the line side was 0.568 amperes when the line to the State border was used, and 1.125 amperes when the entire line to Lindale was connected to the bank. The frequency was 59 cycles.

It is possible to calculate the third harmonic current which should flow in the closed delta, but since this current unfortunately was not measured, no check can be obtained.

In accordance with equation (25) the distribution of third harmonic currents is given by

$$I_2''' = I_n'''\,\frac{Z'''}{Z_2'''}$$

Using this equation the third harmonic currents in the delta winding referred to the high-tension side become:

Line Gadsden—State border:

$$I_2''' = 0.568\,\frac{26.8 - j\,566 \times \dfrac{177}{176.7}}{19.7 + j\,254 \times \dfrac{177}{180}}$$

$$= 0.568\,\frac{567}{250} = 1.29 \text{ amperes.}$$

Line Gadsden—Lindale:

$$I_2''' = 1.125\,\frac{12.8 - j\,332 \times \dfrac{177}{176.7}}{19.7 + j\,254 \times \dfrac{177}{180}}$$

$$= 1.125\,\frac{333}{250} = 1.50 \text{ amperes.}$$

Applying the ratio of transformation, the actual third harmonic circulating current in the 22-kv. delta would be 6.45 amperes and 7.50 amperes respectively for the two cases considered.

SUMMARY

The paper has discussed the distribution of harmonics in single-phase transformers and in three-phase banks of single-phase transformers. Two-winding transformers, or three-winding transformers where the harmonic current exists in two of the windings only, have been considered. The impressed voltages have in every case been assumed strictly sinusoidal so that all harmonics originate in the transformers themselves. If the impressed voltages are non-sinusoidal the problem becomes much more involved and may be considered beyond the scope of this paper.

Formulas for the distribution of harmonics between primary and secondary circuits have been given for a series of connections. These formulas, slightly modified, may also be applied to two secondary circuits, and in general formulas of the same type will give the distribution between *any two circuits* provided no other circuit carries any of the harmonic currents whose distribution is desired.

The harmonic currents distribute themselves between two circuits in inverse proportion to the ratio of the total impedances of the two circuits at the particular frequency considered. The part that the transformer or each transformer in a bank contributes to these impedances is the true leakage impedance of each of the two windings involved with respect to the other winding.

The distribution of the third harmonic current between two circuits has been examined by laboratory tests on small experimental transformers. Y–Δ–Δ and Δ–Y connections were used. The Δ–Y bank was loaded by a Y-connected capacity load and also by a Y-connected load consisting of inductance and capacity. The inductance and capacity in the latter

case were adjusted so as to produce triple frequency resonance in the secondary circuit. The neutral point of the Y-connected load and the neutral point of the transformer bank were in every case interconnected.

The measured and calculated distribution of third harmonic current in the first two tests check to engineering accuracy. The results from the third test could not be used for checking purposes since the reactors employed as a part of the load had iron cores and, therefore, had a tendency to introduce harmonics themselves.

The paper has further given some data and results from a series of field tests on a bank of three 2100-kv-a., 110,000-22,000-2300-volt transformers and a short transmission line. The tests of particular interest in connection with the present subject consisted of determining the separate leakage impedances of two of the windings of the transformers and of measuring the third harmonic current in the line-side neutral when the line was connected to the bank. The transformer connections during the latter tests were Y-open Δ-Y with secondary neutral point grounded.

The third harmonic current in the neutral has been computated from the measured value of the third harmonic voltage across the open corner of the delta winding in connection with the proper combination of transformer leakage impedance and line impedance. The check between the computed and measured third harmonic currents must be considered satisfactory.

List of Symbols

V = Terminal voltage
V_Δ = Voltage across the corner of an open delta winding
E = Induced voltage
E_C = Voltage induced by flux in the core
I = Current
I_Δ = Circulating current in a closed delta winding
I_n = Current in neutral
R_m = Resistance in the corner of a closed delta winding containing meters, etc.
Z_Δ = Total impedance of a closed delta circuit
Z_n = Impedance of neutral

Subscripts attached to the above symbols refer the quantities to the particular winding designated by the subscript.

f = Frequency
C = Capacity
Z_{pri} = Impedance of a primary circuit
Z_{sec} = Impedance of a secondary circuit
Z_G = Generator impedance
Z_L = Load impedance
Z_{11}, Z_{22}, Z_{33} = Self impedance of windings No. 1, No. 2, and No. 3
Z_1, Z_2, Z_3 = Leakage impedance of windings No. 1, No. 2, and No. 3 with respect to some specified winding
R_1, R_2, R_3 = Resistance of windings No. 1, No. 2, and No. 3
X_{11}, X_{22}, X_{33} = Self reactance of windings No. 1, No. 2, and No. 3
$X_{12} = X_{21}$ = Mutual reactance of winding No. 1 and No. 2
$X_{13} = X_{31}$ = Mutual reactance of winding No. 1 and No. 3
$X_{23} = X_{32}$ = Mutual reactance of winding No. 2 and No. 3
X_1, X_2, X_3 = Leakage reactance of windings No. 1, No. 2, and No. 3 with respect to some specified winding
X_L = Load reactance, inductive reactance
X_C = Capacitive reactance

Several of the above quantities are different for the various harmonics. Primes attached to these quantities indicate the order of the harmonic.

Resolution of Transformer Reactance

Into Primary and Secondary Reactances

A. BOYAJIAN[1]

***Synopsis.**—The stand is taken that the resolution of the leakage reactance of a pair of windings into the individual reactances of the two windings is indeterminate unless referred to a third winding and that therefore it varies with the object in view when making the resolution. If the object is the influence of exciting current on performance, the problem is converted into a three-winding transformer problem by conceiving of the exciting current as produced by a (fictitious) load in a (fictitious) third winding. It is pointed out that the resolution of leakage reactance into individual reactances is possible only in the case of three windings, and that therefore in a transformer with three real windings and a fictitious exciting-current-load winding, constituting the equivalent of a four-winding transformer, the simple resolution fails, each winding having a different individual leakage reactance when associated with one pair of the remaining windings than when associated with another pair. Furthermore, the resolution made from the standpoint of real load currents will be different from that made from the standpoint of exciting current. Formulas are given for such resolutions, and experimental methods are described. The problem is also considered from the standpoint of flux distribution and linkages, and the limitations of some common views are pointed out.*

INTRODUCTION

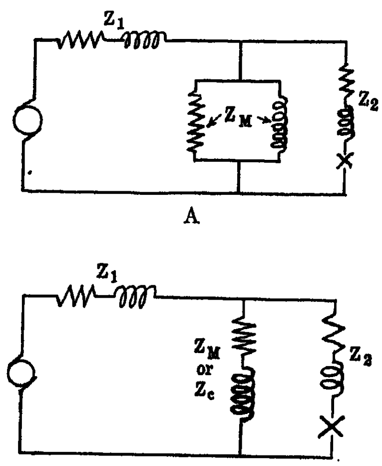
THE old puzzle of the division of the leakage reactance of a transformer into primary and secondary reactances is usually discussed with the tacit assumption that such a division exists in nature,—definite, inherent and absolute,—and that our problem is merely to ascertain its value. But the resolution of the leakage reacttance of two windings into the reactances of the individual windings is no more determinate than the resolution of the distance between two points, A and B, into two parts, one as A's distance, and the other as B's distance. For this reason, it is frequently reported by

1. Technical Engineer, General Electric Co.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, N. Y., June 22-26, 1925.

investigators that the experimental separation of the primary and secondary reactances has failed.

However, if the resolution is desired, not for pure philosophic interest but for a definite concrete object in view, then this object furnishes us the point of view relative to which the resolution is to be made, and the problem becomes determinate. In every instance



A

B

FIG. 1

where an investigator reports that he has found a means of experimentally segregating the primary and secondary reactances, it will be found that he has referred the resolution to some arbitrary point of reference, probably very useful and valid for his purpose, but arbitrary just the same.

The resolution of leakage reactance into primary and secondary reactances is sometimes necessary for certain practical purposes, as shall be illustrated below, but it will be found in every instance that the resolution which is valid for one purpose is not valid for other purposes, and that, therefore, any such resolution has to be relative and conditional.

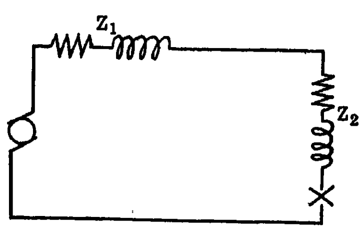


FIG. 2

THE EQUIVALENT CIRCUIT

The classical treatment of a transformer is by means of its equivalent circuit (Fig. 1A or 1B). If the exciting current is ignored, the equivalent circuit becomes like that shown in Fig. 2. If the exciting current is ignored, and the transformer is assumed to have both a secondary and a tertiary winding, then the equivalent network becomes like that shown in Fig. 3. Comparing the equivalent network of a two-winding transformer, which draws an exciting current, (Fig. 1A or 1B, especially the latter), with the equivalent network of a three-winding transformer which draws no exciting current, (Fig. 3), the essential identity of the two becomes evident. That is, the standard equivalent circuit of a transformer (Fig. 1) treats the exciting current as though it were a (fictitious) load-current drawn from a (fictitious) third winding. From this standpoint, the resolution of leakage reactance into separate primary and secondary reactances becomes a three-winding transformer problem, the general solution of which has been accomplished within the last few years[2] and which we may briefly review here.

GENERAL THEORY OF THREE-WINDING TRANSFORMER

In considering the effect of the impedance of a three-winding transformer on its performance, such as regulation, short-circuit current, division of load, etc., we may resolve the leakage impedances between pairs of windings into impedances of the individual windings, the only condition to be satisfied beings, that, symbolically,

$$Z_1 + Z_2 = Z_{12} \quad (1)$$

$$Z_2 + Z_3 = Z_{23} \quad (2)$$

$$Z_1 + Z_3 = Z_{13} \quad (3)$$

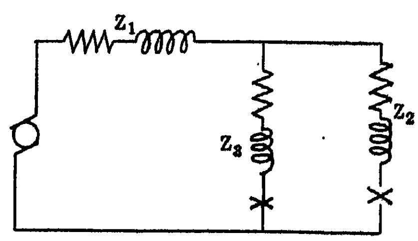

FIG. 3

It may be evident from these equations that the resolution of Z_{12} into Z_1 and Z_2 is made dependent on winding No. 3 by involving Z_{13} and Z_{23}, so that if winding No. 3 is altered the resolution of the leakage reactance between windings No. 1 and No. 2 into Z_1 and Z_2 is also altered. Certainly, any such resolution that is made variable with changes in a third winding cannot be considered absolute or inherent but must be considered purely relative. Generalizing, we may say that a winding may be said to have a definite individual leakage reactance only with reference to two other windings. Referred to less than two other windings, the individual leakage reactance of a winding is indeterminate, any resolution being as good as any other, and all of them being equally needless. Referred to more than two other windings, the reactance characteristics of a winding cannot be completely specified by a single value.

2. Transformers for Interconnecting High Voltage Transmission Systems by J. F. Peters and M. E. Skinner. JOURNAL A. I. E. E., June 1921, Vol. XL, page 483.

Theory of Three-Circuit Transformers, A. Boyajian, JOURNAL A. I. E. E., 1924, Vol. XLIII, page 345.

Application to Two-Winding Transformers

In a two-winding transformer the resolution of the leakage reactance into primary and secondary reactances having a significance only in relation to the exciting current, and the exciting current being conceivable as occasioned by a load in a fictitious third winding, the desired resolution, in the light of the theory of three-winding transformers, may be defined as follows. Let C represent the fictitious third winding which simulates the characteristics resulting from the core. The leakage reactances between this fictitious winding C and the real windings No. 1 and No. 2,

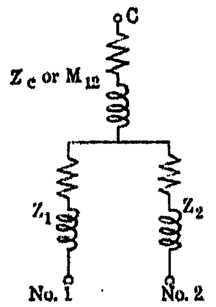

Fig. 4

respectively, may be designated as X_{1c} and X_{2c}. The individual leakage reactances X_1 and X_2, resolved with respect to the exciting current, will be given by

$$X_1 = (X_{1c} + X_{12} - X_{2c})/2 \qquad (7)$$

$$X_2 = (X_{2c} + X_{12} - X_{1c})/2 \qquad (8)$$

$$X_c = (X_{1c} + X_{2c} - X_{12})/2 \qquad (9)$$

The equivalent network of this resolution, as that of a three-winding transformer, is shown in Fig. 4, which is another form of Fig. 1B.

It may be noted that the core exercises a controlling influence on the resolution when made with reference to exciting current, (even though its effect on the total leakage reactance is ordinarily small), but it exercises no direct influence on the resolution when made with reference to load currents as in a three-winding transformer.

If it is desired to consider the element of exciting current in a three-winding transformer, the problem becomes one of four-windings, the exciting current being represented as a load in a fourth (fictitious) winding, as outlined above. In this case no definite, consistent reactance values can be assigned to the windings to indicate their performance rigorously from the standpoint of exciting-current. Furthermore, even if this could be done, the reactance values so assigned would be inconsistent with the values required to represent their load characteristics properly.

Individual Leakage Reactances in Terms of Self and Mutual Reactances

Considering the equivalent network of a two-winding transformer with its fictitious third circuit, C, (Figs. 1B and 4), it will be evident that the impedance, Z_c, is in series with and common to both of the circuits No. 1 and No. 2, and may, therefore, be recognized as the mutual reactance M_{12} between the two circuits. Z_{1c} will be recognized as the open-circuit, self inductive reactance of circuit No. 1, which we may designate as Z_1', Z_{2c} as that of No. 2, which we may designate as Z_2'. Evidently,

$$Z_1 = Z_{1c} - Z_c \qquad (10a)$$

$$= Z_1' - M_{12} \qquad (10b)$$

$$Z_2 = Z_{2c} - Z_c \qquad (11a)$$

$$= Z_2' - M_{12} \qquad (11b)$$

$$Z_{12} = Z_1 + Z_2 \qquad (12a)$$

$$= Z_1' + Z_2' - 2\,M_{12} \qquad (12b)$$

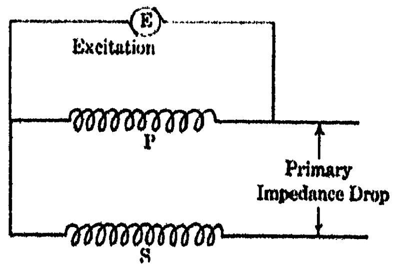

Fig. 5

Equation (12b) will be recognized as classcial. Equations (10b) and (11b) have been used in the past[3] to define the individual reactances Z_1 and Z_2, but no recognition has been made of their relativity with respect to the exciting current so far as the present writer is aware. These equations (10b) and (11b) if derived directly, based on the reasoning that the total

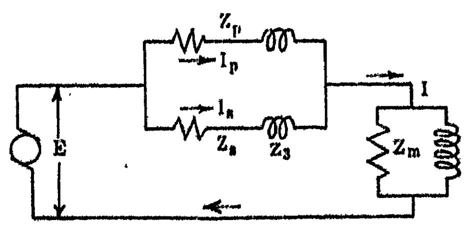

Fig. 6

voltage induced in the winding is the difference between the self-inductive voltage drop and the mutual voltage induced from the other winding, have the appearance of finality. However, when they are derived, as a special case of a three-winding transformer, even though the derivation is roundabout, it is believed that the relativity of the resolution is thereby made clear. So far as utility for practical computation is concerned, neither the set of equations (7), (8), and (9), nor the set (10b), (11b), and (12b) is of a great deal of value. Their primary use is to define the quantities to which

3. See, for instance, Rogowski, Dispersion in Transformers, *ETZ*, Vol. XXXI, pp. 1033-1036, 1069-1071; also, Mitteilungen uber Forschungsarbeiten, Heft. No. 71.

they refer and thus suggest and guide practical methods of calculation.

Experimental Resolution

Consideration of the equivalent circuit of a two-winding transformer, (Figs. 1 and 4), suggests a variety of test methods for the determination of X_1 and X_2. They are very simple and convenient for transformers with 1:1 ratio. Those with other ratios will require either current or potential transformers of the same ratio as their own and the results will naturally be complicated on account of errors of ratio and phase angle introduced by these auxiliary transformers.

1. *Regulation due to Exciting Current.* The primary impedance drop, due to exciting current, can be measured directly and very exactly in a 1:1 ratio transformer by using the connection shown in Fig. 5. Knowing the current and the impedance drop, the value of the impedance follows by Ohm's law. If the transformer ratio is not unity, a potential transformer of the same ratio would be necessary for the test.

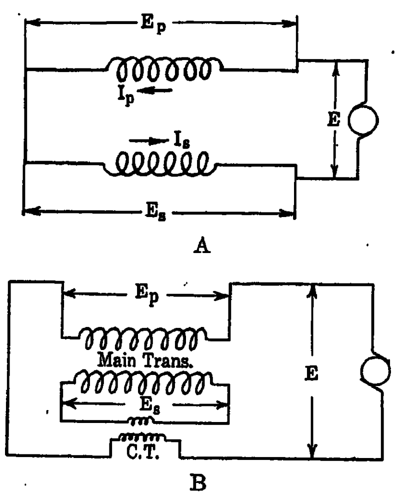

Fig. 7

2. *Division of Exciting Current.* If the two windings (1:1 ratio) are excited in parallel, they must divide the exciting current inversely as their respective leakage impedances. The equivalent circuit diagram of this test condition is shown in Fig. 6. When the ratio is not unity, the windings may be paralleled through a suitable current transformer.

3. *Series Impedance Test.* With the two windings connected in series opposition, (Fig. 7A), the voltage-drop across each winding can be measured directly, and knowing the current, the individual leakage impedances follow by Ohm's law. With ratios other than unity, the two windings may be connected in series through a suitable current transformer (Fig. 7B), although the results are likely to be disturbed by the errors of ratio and phase angle of the current transformer.

4. *Parallel Impedance Test.* If the two windings are excited in parallel-opposition, (Fig. 8), so that the core cannot be magnetized as a whole, the impressed voltage must be balanced by the leakage impedance of the two windings, and the division of current between them will be inversely as their respective leakage impedances.

Absolutely consistent results need not be expected from all these tests. In fact, the results will vary somewhat with varying values of current and voltage even when using the same connection. The reason for this is that changes in the permeability of the core at various densities affect differently the reluctances of the external and internal parts of the magnetic circuit, neither the

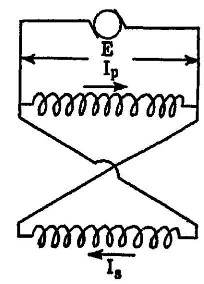

Fig. 8

iron magnetic circuit nor the air magnetic circuit (which are in parallel) having uniform section or length. This fact was forced to the attention of the writer in 1921 while investigating the division of third harmonic current between transmission lines and internal deltas. The method of test and some of the results bearing on the present discussion were as follows:

5. *Third Harmonic Tests.* The division of exciting current, described under test method No. 2, would, of course, apply to the higher harmonics of the exciting current as well as to its fundamental, at least to a first approximation. Hence, if two parallel paths are offered to the flow of the third harmonic exciting current, as for instance by two delta-connected wind-

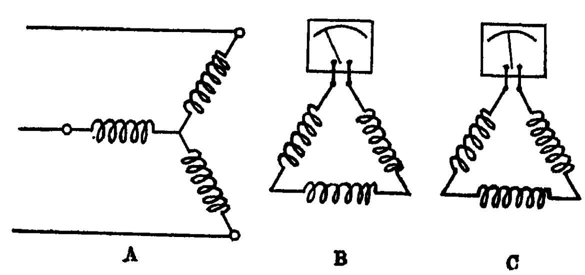

Fig. 9

ings, (Fig. 9), the division of the third harmonic exciting ampere-turns between them must be inversely as their respective leakage impedances. Hence, having obtained the division of current by test, the division of the leakage impedance between the two windings follows as indicated.

The foregoing method was tested on a three-phase bank of two-legged core-type transformers having a number of concentric windings on both of the legs. One set of windings was connected in Y for excitation, and two sets were connected in delta, (Fig. 9). The

two delta windings had the same current and voltage rating and had low impedance between them, their 60-cycle leakage reactance being about three times their resistance. Both of the delta windings were on one and the same leg of the core. The *Y* primary windings were chosen on the same leg as the delta windings in one set of tests (marked Case I. below), and on opposite leg in another set of tests (marked Case II. below), to observe the effects of low and high reactances between the primary winding and the two secondary delta windings, with results as follows:

	Nominal flux density in core	Third harmonic circulating current in each unit in per cent of the total third harmonic current Delta *B*	Delta *C*
Case I.	38 Kilolines/sq. in.	51 per cent	49 per cent
	112 " " "	44 per cent	56 per cent
Low Reactance			
Case II.	43 " " "	48 per cent	52 per cent
	113 " " "	53 per cent	47 per cent
High Reactance			

It is of interest to note how the division of current (and reactance) changes with a change in core density, and also how the direction of change with high reactance primary is opposite from that with low reactance primary. It may be remembered from earlier discussion that this is really a four-winding problem,—three real and one fictitious windings, and that the treatment of this as a three-winding problem, that is as two real (delta) windings and one fictitious winding representing the core, is justifiable only at the lower densities, where the primary exciting current and the corresponding flux in air are small, as confirmed by the fact that Cases I and II given above approach each other at the lower density.

The Viewpoint of Flux Distribution and Linkages

Discussion of reactances by transformer engineers is frequently expressed in terms of flux linkages. This is the designer's point of view, and has its uses in the determination of losses. As this involves a more detailed analysis of the transformer, one might be led to consider it more basic and accurate. However, as ordinarily handled, it has serious limitations. For instance, a common statement by transformer specialists is that most of the reactance of a transformer (say 80 per cent to 90 per cent), is primary reactance and that only a small portion (say 10 per cent to 20 per cent), is secondary reactance. Such a view, although conceding the relativity of individual reactances by assigning the reactance primarily to the excited winding, fails by not distinguishing between main and leakage fluxes and their composite. The basis commonly cited for the assignment of the total or major part of the reactance to the excited winding is briefly as follows: Ignoring the small resistance drops of the windings for simplicity, the net flux-linkages of each winding must be proportional to its terminal voltage. But on the impedance test the secondary terminal voltage is zero, and hence its net flux-linkages must be zero. This condition, however, does not require that no portion of the secondary should link any flux. Since windings must have some thickness, and leakage flux within their thickness, partial flux-linkages of the short-circuited secondary cannot be avoided, the magnitude and sign of these partial linkages being such as to add up to zero. In making such an analysis it is found that the major part of the flux links exclusively the excited winding, a small part links both the excited winding and the short-circuited secondary, and another small part (equivalent and opposite to the preceding) links exclusively the short-circuited secondary. Basing the resolution of reactance on such a resolution of fluxes, if net flux-linkages alone are considered all reactance becomes primary and none secondary; and if the partial exclusive flux-linkages of the secondary are featured, a small fraction of the total reactance becomes secondary. However, this plausible reasoning

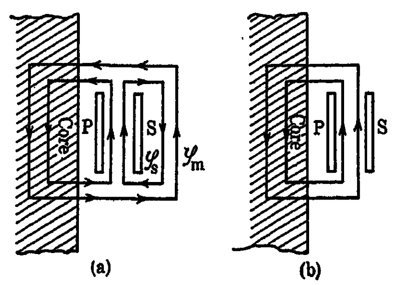

Fig. 10

fails by confusing the total short-circuit flux with the leakage flux. The flux distribution and linkages hinted above are true only for the resultant of the main and leakage fluxes, and therefore the distribution or linkages of the latter cannot be considered a direct measure of the distribution of the leakage reactance. It would be erroneous to assume that there is no main flux under the impedance test condition, even ignoring the resistance of the windings. Main and leakage components of the flux may cancel in the short-circuited winding, and add up in the excited winding, as illustrated in Figs. 10a and 10b; but the fact that the linkages of the *resultant* flux with the secondary is zero could not be taken as a proof that the leakage reactance of that winding is zero, as this can be proven only by segregating the leakage flux proper and determining its linkages. The two component fluxes, under the impedance test condition, are so intimately merged into each other that their segregation, if attempted by measurements made on the composite flux, is most discouraging, as has been the experience of many an

investigator[4]. The practical solution of the problem would rest in making measurements under conditions in which only one kind of flux exists at a time: (a) leakage flux unmixed with main flux in one case, (b) main flux unmixed with leakage flux in the other. Condition (a) is realized by connecting primary and secondary windings in series-opposition (one to one ratio) in which case no exciting current and hence no main flux can exist. Condition (b) is realized by open-circuiting the secondary, so that no load current, and hence no leakage flux, can exist, and impressing on the primary a voltage equal to the secondary impedance drop measured in the preceding case. One small limitation must be borne in mind that due to the differing permeability of the core at different densities, the flux distribution and linkages for the resultant flux will not follow exactly the calculated values based on linear combinations of the two components.

CONCLUSIONS

(1) The idea of individual leakage reactance for circuits inductively related to each other is a very convenient conception for certain purposes; however, the resolution is not inherent and absolute, but is purely relative, and is workable only when the problem is theoretically resolvable into three circuits. With less than three circuits, the resolution is indeterminate, and with more than three circuits, it is not possible.

(2) In a two-winding transformer, such a resolution can have a significance only with respect to the exciting current. The resolution is then defined (in terms of three-winding theory) by conceiving the exciting current as caused by a load in a fictitious third winding.

(3) As a practical definition, the individual reactances of a two-winding transformer may be defined as the apparent individual reactances of the two windings in series-opposition connection, on the basis of 1: 1 ratio. Other methods of test are also described in the text, but perfect agreement among the various methods cannot be expected on account of the varying permeability of the core at the different densities involved. The different densities will influence the division of reactance very sensibly, even though they may not affect the total reactance appreciably.

(4) In a three-winding transformer, it is not rigorously possible to assign a definite individual leakage reactance to each winding with reference to exciting current, but it is possible to do so with reference to their load currents.

(5) Flux distribution and linkages under the short-circuit test condition apply to the resultant of a main flux and a leakage flux and therefore may not be taken as a direct measure of the division of leakage reactance between primary and secondary windings.

4. See for instance, K. B. McEachron, "Magnetic Flux Distribution in Transformers," JOURNAL A. I. E. E., 1922, pp. 281-287.

It may be noted that in the simple case of a perfectly symmetrical magnetic circuit (ignoring the resistance and thickness of the secondary), the main flux ϕ_m and the leakage flux ϕ_s (shown in Fig. 10A for the impedance test condition) wipe out each other bodily where they fall together, as in the return leakage field of the secondary, and the resultant flux in this region becomes zero, as shown in Fig. 10B. In actual transformers, the distribution of main and leakage fluxes in the return field are neither alike nor uniform, and, therefore, although the two will still neutralize one another's total linkages, they will not wipe out each other's fluxes at every point in the return path of the secondary leakage field, and some of the secondary leakage flux will retain its identity. It is this partial flux which is sometimes erroneously taken as the measure of secondary leakage reactance.

RESOLUTION OF TRANSFORMER REACTANCES INTO PRIMARY AND SECONDARY REACTANCES
(BOYAJIAN)

SARATOGA SPRINGS, N. Y., JUNE 25, 1925

J. F. Peters: In Mr. Dahl's paper, as far as I can see, the assumption is made that the triple-frequency component of magnetizing current follows Ohms' law, that is, there is inherently in the transformer a triple-frequency voltage and the triple-frequency component of current that will flow is that voltage divided by a triple-frequency impedance. If this is the case, then by decreasing the triple-frequency impedance to a small value, the corresponding current could be made quite large. Obviously this cannot be the case because when the triple-frequency current reaches a certain value, which is approximately 40 to 45 per cent of the fundamental-frequency current, the voltage wave takes on a true sine shape in which case the triple-frequency voltage disappears. It may not be possible to decrease this impedance to a very small value within the transformer, but if it is a true impedance, it can be counteracted to any desired degree externally. Also, if no triple-frequency current is permitted to flow, there will be a large triple-frequency voltage appear across each of the phases. In a transformer of commercial proportions and flux density, this voltage would amount to approximately 75 per cent of the fundamental-frequency voltage, which, in the transformer analyzed by Dahl, would amount to 100 volts triple-frequency. Then the triple-frequency current that should flow in any winding should be that voltage divided by this triple frequency impedance. He finds in winding one a triple-frequency impedance of approximately one-half ohm. This should give a triple-frequency current in the order of 200 amperes. Actual measurements show approximately two amperes.

Since this triple-frequency impedance is not a true impedance, that is, its X value is not a consonant, there are a number of operations used by Mr. Dahl that may be questionable. For instance, in his paper on *Transformer Harmonics, etc.*, on the seventh page, first column, paragraph 3, in measuring the triple-frequency current in two delta windings, when measuring the current in one winding, the corresponding resistance in the other winding was short-circuited in order to use the same measuring instrument in both, and vice versa. This resistance in the measuring instrument is quite large. It is of the order of the total impedance of the winding. That means,

in shifting from one winding to another, the triple-frequency current distribution between the windings has been changed, and since the triple-frequency impedance obtained applies only to the particular flux density and triple-frequency current under which the test was made, there is a chance for considerable error being introduced.

There is another point in connection with the paper that makes me feel that perhaps something not permissible was done. Mr. Dahl determined the triple-frequency impedance of his transformer by two methods: In the two-winding methods, he determined X_3 between coils 1 and 3 and found the value to be 1.275. By means of the three-winding method, he determined X_3 between windings 2 and 3 and found it to be 1.336. The distance between coils 2 and 3 is three-quarters of an inch. The distance between coils 1 and 3 is approximately 0.95 in. That being the case, the reactance X_3 measured between coils 1 and 3 should be approximately 25 per cent higher than measured between coils 2 and 3. Actually, he finds it to be approximately 96 per cent, so that there is a considerable discrepancy between X_3 measured by the two methods of the order of 25 or 30 per cent. That could hardly be considered within engineering accuracy.

The methods used by Mr. Boyajian are so simple and direct that I feel the chances of error are very remote and you will note in his one set of tests that he gives the distribution of triple-frequency current between two delta windings, that distribution changes with flux density which also shows the fictitious triple-frequency impedance is not a true impedance but changes with conditions.

V. Karapetoff: Consider a two-winding transformer, with or without an iron core, and disregard saturation and core loss. Such a transformer can be first replaced by one of one-to-one ratio of turns, and then by an equivalent diagram shown in Fig. 1 of Mr. Boyajian's paper (with a pure reactance in the exciting branch). In this diagram, the values of the leakage reactances Z_1 and Z_2 are perfectly definite, namely $Z_1 = Z_1{}^1 - X_{12}$ and $Z_2 = Z_2{}^1 - X_{12}$, where $Z_1{}^1$ and $Z_2{}^1$ are the total impedances of the windings (leakage plus mutual flux) and X_{12} is the mutual reactance. Therefore, rather than convey an impression that eakage reactances are fictions valid for one purpose and not valid for other purposes, would it not be better to say that in a two-winding transformer these reactances have a definite meaning in the equivalent diagram and must be interpreted in the actual transformer with reference to this equivalent diagram?

In a transformer with more than two secondaries, the indefiniteness of the division of the leakage fluxes among the individual windings lies in the very nature of the phenomenon. Consider for example a "split" single-phase line, consisting of two lines on adjacent cross-arms. The inductance of such a line depends upon the fractions of the total load carried by the two loops, and is different for different divisions of the load.

R. G. McCurdy: It seems to me that Mr. Boyajian is in error in stating that the difficulties which have arisen in dividing leakage impedances between windings are due to any lack of definiteness of the problem. The generally acceptable definitions of the individual leakage reactances are given by equations (**10b**) and (**11b**) of his paper. In two-winding transformers, when the exciting current is ignored, a single leakage impedance equal to the sum of the two individual leakage impedances may be used in computing regulation under load, and with three-winding transformers ignoring the exciting current leads to the set of equations (1) (2) and (3) of his paper which express individual impedances in terms of the total leakage impedances between pairs of windings. I think it leads to confusion, however, to call such individual impedances of three-winding transformers "individual leakage impedances."

When it is desired to determine division of exciting currents between different windings the above simplifying assumptions may not be made. Knowledge of the individual leakage reactances is then necessary. With two-winding transformers the simple equivalent network of Fig. 1 of Mr. Boyajian's paper may be used. This same network will also apply when considering the division of harmonic exciting currents in three-winding transformers when one of the windings is connected so that current of that frequency is suppressed. When current may flow in all three windings a more complicated network must be set up involving in general seven impedance elements.

While it is true that fairly simple arrangements may be used for determining the individual impedance of unity-ratio transformers, the application of such methods to transformers of other ratios presents difficulties. Take for example the circuit of Fig. 7B of Mr. Boyajian's paper. An equivalent circuit is shown in the appended Fig. 1. It will be evident by inspection that if the ratio of the secondary leakage impedance to the exciting impedance is the same for both the transformer under test and the current transformer, the secondary voltage will be zero and the primary voltage will be the same as that obtained on a

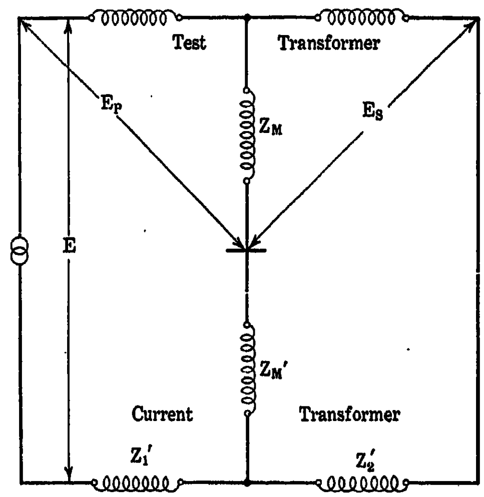

FIG. 1—CIRCUIT EQUIVALENT TO FIG. 7 OF BOYAJIAN PAPER WITH CURRENT TRANSFORMER

short-circuit test. To determine the individual leakage impedances accurately by such a scheme, the secondary leakage impedance of the current transformer would need to be very low and the exciting impedance very high as compared to the corresponding quantities of the transformer under test. Similar difficulties arise in the use of potential transformers in determining the division of exciting currents between the windings. Mr. Boyajian erroneously refers to the use of current transformers for this purpose.

For these reasons such methods for determining the individual leakage impedances do not seem to have much practical importance. Methods based upon the division of triple-harmonic exciting currents as discussed by Mr. Dahl appear to be more useful.

I note in comparing the test results of Mr. Boyajian and Mr. Dahl a considerable difference in the effect of magnetic density on the individual leakage impedances. I wonder if they have been equally careful to eliminate the impedances of measuring instruments and the effects of fundamental and harmonics other than the third. If I read Mr. Dahl's paper correctly he has largely eliminated errors due to these sources.

J. F. Peters: In view of what Mr. McCurdy stated I would like to amplify a point that I intended to make in the first discussion. I feel that the method that Mr. Dahl has used is of considerable value in many applications but it must be carried on with great care. The point I wanted to bring out was that the impedance obtained by this method applies only to that particular flux

density and value of triple-frequency current, that it is not a true impedance. Care should be taken to retain the currents in their normal values. It is very unfortunate in the tests of the two deltas that Mr. Dahl made that it was necessary to short circuit the resistance in one delta while measuring current in the second. This is more nearly a constant-current proposition than it is a constant-potential proposition. That is, if you were to insert in the corner of the delta sufficient impedance to reduce the current to one-half of the value, the residual triple-frequency voltage would be more than double. It will not follow that law at all and I feel that there may be some considerable errors in the actual values obtained by means of changing the distribution of current.

L. P. Ferris: Without entering into the technical controversy that appears between the papers by Messrs. Dahl and Boyajian, I wish to point out one example of the practical importance of a solution of this problem of the division of impedances between transformer windings. The example to which I have reference arises in connection with the inductive relations between power circuits and neighboring telephone circuits. When the neutrals of transformers are grounded it is important to know how the triple-harmonic exciting currents divide between the several windings of the transformer and particularly how these currents divide between closed deltas and the windings which are connected to the lines with grounded neutrals. This is a practical problem of great interest in addition to the problems of the effect of these impedances on regulation and on the division of load between windings.

It will be appreciated that this distribution of the triple-harmonic currents is a perfectly definite thing which is determined in practise as soon as the transformer is connected to the line and is controlled by the characteristics of the transformer and of the line. The transformer impedances involved may be called by the term "leakage impedance" or by some other term. However, there is this very definite distribution which takes place and it is necessary to carry our analysis to the point where this distribution may be predetermined. Thus it may be possible to predetermine the effect of a given change in connections or the effect of the addition of a new bank of transformers in a complicated network.

This problem was encountered by Mr. McCurdy, Mr. Cone and myself about ten years ago in connection with our work in California with the Joint Committee on Inductive Interference. There are discussions of it in several of the technical reports of that committee which have been published by the California Railroad Commission.

The interest which is now being manifested in this subject by the colleges and several manufacturing concerns is very gratifying and I hope that it will continue until a common understanding is reached. This problem is one which is now engaging the attention of the Joint Subcommittee on Development and Research of the National Electric Light Association and the Bell System and I am sure that this committee will welcome any contributions to a solution by engineers either from the manufacturers or from the colleges.

C. T. Weller: I would like to discuss the subject of transformer reactance with particular reference to instrument transformers.

The use of instrument transformers has been referred to by Mr. Boyajian, so I will first comment on that. He states, under "Experimental Resolution," that when instrument transformers are used, the results will be complicated on account of the errors of ratio and phase angle introduced thereby. The ratio and phase-angle errors of properly designed instrument transformers are very small and can be very accurately determined if the condition of use can be reproduced in the calibration. If I understand the diagrams correctly, the condition described in Paragraph 1 can be accurately reproduced, but this is not the case with respect to Paragraphs 2 and 3, because it is entirely possible that the excitation of the instrument transformer may be wholly or partly supplied from the secondary due to differences in the characteristics of the transformers. I believe that the reference in Paragraph 2 should be to a potential rather than to a current transformer. In this connection, I would like to emphasize the point, which has already been made, that the detectors used in these tests may considerably complicate the results.

Instrument transformers are usually two-winding transformers with the primary surrounding the secondary. We have determined the approximate individual leakage reactance of the windings of a few of our standard transformers by calculation from the ratio and phase-angle and exciting-current results. The results are somewhat indeterminate due to the very small errors of the transformers. I might add here that in transformers of this grade, the effect of third and higher harmonics is negligible.

For potential transformers of moderate voltages, the primary leakage reactance may be taken to be about one-half of the total reactance obtained from the short-circuit impedance test. The range of phase angle, for the limiting cases of first assuming that the primary has zero leakage reactance, and second, that all the leakage reactance is concentrated in the primary, may not exceed five minutes. This indicates that the phase-angle error is very small. The leakage reactance appears to be constant under all normal load conditions. The total impedance and reactance appear to be the same at rated voltage as at the low voltage obtained in the impedance test. This makes it possible to determine in advance rather than to obtain by trial the power factor of the output which will give the maximum ratio error.

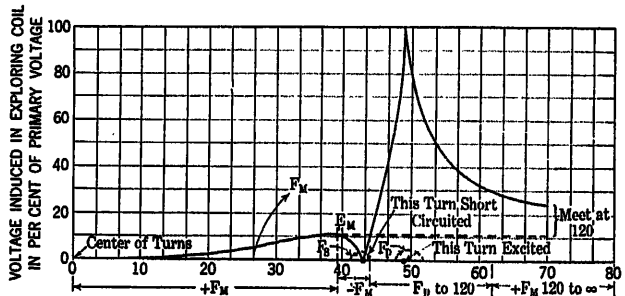

Fig. 2

For current transformers of the ring-core type, with evenly distributed windings, the secondary leakage reactance may be taken to be zero. For current transformers of moderate voltage ratings and of low ratios of the square-core type, the leakage reactance may be taken to be approximately one-quarter of the total leakage reactance obtained from the short-circuit impedance test. This value applies over the range of rated current. For moderate overloads, the value may reach over one-half of the total leakage reactance. At heavy overloads, the saturation of the core greatly complicates the results.

To sum up, the approximate division of the leakage reactance of the windings of instrument transformers has been given for a few cases. These results were obtained by calculation from the ratio and phase-angle and exciting-current results and were referred to the results of the short-circuit impedance tests. This method is applicable to any two-winding transformers.

K. K. Palueff: In regard to the Resolution of Reactances, it is perhaps of interest to see the results of theoretical analysis of an elementary transformer. They are two concentric circles in air (one of which serves as primary and the other as secondary). These results can best be presented in graphic form.

Fig. 2 herewith gives voltage induced in exploring coils of various diameters placed concentrically with the circles and in the same plane. This voltage is expressed in per cent of total voltage induced in primary (which in this case is the outer circle).

Fig. 3 gives voltage distribution in case the inside circle is primary.

In both cases the secondary circle is short circuited and is assumed to be of zero resistance. These examples are calculated for circles of 43 and 49 centimeter radius and round conductors of one centimeter diameter.

From the curves the direction and density of the flux in the plane of the circles can be determined.

In Fig. 2 we find that beginning from the center the voltage increases to a certain point (E_m) inside of the region enclosed by the secondary circle, and then gradually diminishes reaching zero in the region occupied by the shorter circle. This means that in the region encircled by the secondary there are two fluxes ($+ F_m$, $- F_m$) equal and opposite and with boundary line coinciding with the point of maximum voltage of this region, (E_m).

As we proceed the short-circuited circle toward the excited outer circle voltage is steadily increasing. At a certain point it reaches the value of maximum of the region encircled by a secondary (E_m). This point therefore lies on the outer boundary of the secondary flux ($- F_m$).

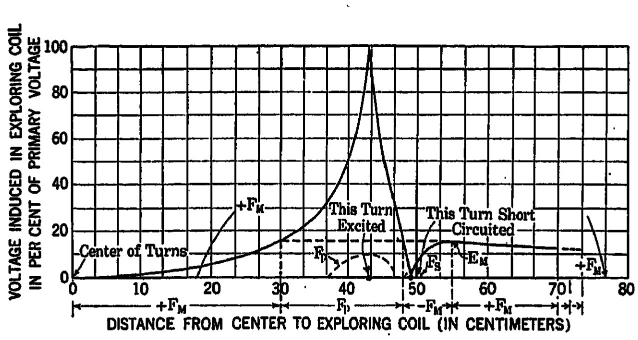

FIG. 3

After passing the primary turns voltage begins to diminish and at certain points reaches again the value of maximum of the region enclosed by the secondary, thus marking the outer boundary of flux linking with the primary circle alone (F_p) and of the flux linking with both turns ($+ F_m$).

Fig. 3 gives voltage distribution in case the inner circle is excited and the outer short-circuited.

W. V. Lyon: The method of analyzing the performance of a transformer that Mr. Dahl outlines has some interesting possibilities when applied to three-circuit transformers. It seems to me that it makes clearer some points that Mr. Boyajian brings up in his recent paper on the theory of such transformers.[1]

When three circuits are magnetically coupled the instantaneous terminal potential of one of them may be equated to the sum of four components.

$$v_1 = r_1 i_1 + L_1 \frac{d i_1}{d t} + M_{12} \frac{d i_2}{d t} + M_{13} \frac{d i_3}{d t} \qquad (1)$$

The difficulty met in handling this equation is due to the fact that with an iron magnetic circuit the inductances, both self and mutual, are variables, being functions of the currents. As far as the solution of a great number of problems goes, however, this difficulty can be removed entirely by the following device. While the principle of the device is old, the way of presenting it is not so common, especially in the case of transformers with three windings. The magnetic flux distributions which account for the self and mutual inductances may be divided into two components. By far the greater portion of the flux is confined to the iron core, but a smaller part exists wholly or partially in air. This smaller part, however, determines almost entirely the operating characteristics of the transformer. This thought is interesting.

1. Theory of Three-Circuit Transformer, A. Boyajian. A. I. E. E. JOURNAL, April 1924, p. 345.

At this point we will assume that the flux that is wholly within the iron core depends only upon the value of the ampere-turns producing it, and is entirely unaffected by the position of these ampere-turns with respect to the core. While this is not precisely true the error must be very small. That is to say, this flux that is wholly within the iron is the same whether produced by a given number of ampere-turns in circuit one, two, or three. Let M be the value of inductance assigned to each circuit on account of this flux. This inductance is variable. The remainder of the flux due to any of the circuits is wholly or partly in air and for this reason is essentially proportional to the current in the circuit. In all that follows we will assume that each of the three circuits has the same number of turns. The method of treatment when the number of turns is different is well known. Thus if we subtract from the self and mutual inductances given in equation (1) the inductance M the result in each case will be an inductance of *constant* magnitude, being due to flux that exists wholly or partly in air. Equation (1) becomes

$$V_1 = r_1 i_1 + (L_1 - M) \frac{d i_1}{d t} + (M_{12} - M) \frac{d i_2}{d t}$$

$$+ (M_{13} - M) \frac{d i_3}{d t} + M \frac{d}{d t} (i_1 + i_2 + i_3)$$

The last component is the electromotive force produced in each of the windings by the action of the flux that exists wholly in the iron. Hereafter we will represent it by the letter e, or E, if the equation is written in the vector form. Following the nomenclature that Dahl uses we will write

$$(L_1 - M) \frac{d}{d t} = j x_{11}$$

$$(M_{12} - M) \frac{d}{d t} = j x_{12}$$

and

$$(M_{13} = M) \frac{d}{d t} = j x_{13}$$

Therefore we will now write equation (1) thus:

$$\overline{V}_1 = (r_1 + j x_{11}) I_1 + j x_{12} I_{12} + j x_{13} I_3 + E \qquad (2)$$

Likewise

$$\overline{V}_2 = (r_2 + j x_{22}) I_2 + j x_{12} I_1 + j x_{23} I_3 + E \qquad (3)$$

and

$$V_2 = (r_3 + j x_{33}) I_3 + j x_{13} I_1 + j x_{23} I_2 + E \qquad (4)$$

x_{11} is the self reactance of circuit (1) due to flux that is wholly or partly in air. It is thus a constant quantity. Similarly x_{12} is the mutual reactance between circuits (1) and (2) due to flux that is wholly or partly in air. It is likewise a constant quantity. The meaning of the other reactances x_{22}, x_{33}, x_{23} and x_{13} is at once evident. In order to proceed with the problem effectively and without too much difficulty it is necessary at this point to assume that the sum of the currents in the three circuits, that is the net magnetizing current, is insignificant in comparison with the individual currents themselves. This assumption limits the scope of the solution, but with about full-load current in the circuit it is nearly true. At any rate it is a customary assumption and need cause no concern. Thus we will write equation (5) as

$$I_1 + I_2 + I_3 = 0 \qquad (5)$$

Equations 2, 3, 4, and 5 are fundamental in determining the operation of three-circuit transformers.

The voltage drop between the terminals of circuits (1) and (2) *i. e.* ($V_1 - V_2$) is, if it is noted that $I_3 = - I_1 - I_2$

$V_1 - V_2 = [r_1 + j\ [(x_{11} - x_{12} + x_{23} - x_{13})]$

$$I_1 - [r_2 + j\,(x_{22} - x_{12} - x_{23} + x_{13})]I_2 \qquad (6)$$

Similarly

$$V_2 - V_3 = [r_2 + j\,(x_{22} - x_{23} - x_{12} + x_{13})]\,I_2 - [r_3 + j\,(x_{33} - x_{23} + x_{12} - x_{13})]\,I_3 \qquad (7)$$

Also

$$V_3 - V_1 = [r_3 + j\,(x_{33} - x_{13} + x_{12} - x_{23})]I_3 - [r_1 + j\,(x_{11} - x_{13} + x_{23} - x_{12})]\,I_1 \qquad (8)$$

It will be noted that these last three equations may be written as follows:

$$V_1 - V_2 = Z_1 I_1 - Z_2 I_2$$
$$V_2 - V_3 = Z_2 I_2 - Z_3 I_3$$
$$V_3 - V_1 = Z_3 I_3 - Z_1 I_1$$

The impedances Z_1, Z_2 and Z_3 in these equations are the same as Z_A, Z_B and Z_C that Boyajian uses. In the same way that a two-circuit transformer may be represented by a single coil as in Fig. 4, so a three-circuit transformer may be represented by three coils as in Fig. 5.

Equations (6), (7) and (8) throw some interesting light on the composition of the impedances that are associated with the three equivalent coils shown in Fig. 5; *e. g.*, $x_{11} - x_{12}$ is the leakage reactance between circuits (1) and (2) while $x_{11} - x_{13}$

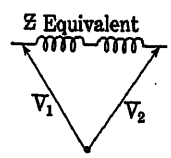

Fig. 4

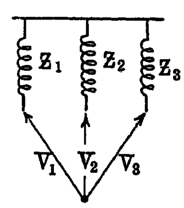

Fig. 5

is the leakage reactance between circuits (1) and (3). The equivalent reactance of circuit (1) is the leakage reactance of (1) with respect to (2) plus the differential effect of (3) upon (1) and (2). If the third circuit were symmetrically located with respect to the other two circuits its mutual effect upon each would be the same; x_{23} would equal x_{13} and the equivalent reactance of (1) would be its leakage with respect to (2) alone. Or, if the third circuit did not carry any current the terms x_{23} and x_{13} would not enter into the equivalent reactance of the first circuit. This also appears if in equation (6) I_2 is equal to $-I_1$, *i. e.* $I_3 = 0$. It will be seen that the drop between the first two circuits is then

$$V_1 - V_2 = [r_1 + j\,(x_{11} - x_{12}) + r_2 + j\,(x_{22} - x_{12})]\,I_1$$

Now it is evident that it is only when $x_{11} = x_{22}$ that the leakage reactance of (1) with respect to (2) is equal to the leakage reactance of (2) with respect to (1). Again, if it is possible to arrange the circuits so that the mutual reactances between circuits (1) and (2) and between (1) and (3) are relatively large in comparison with the mutual reactance between (2) and (3) it may be that the equivalent reactance of circuit (1) will be negative. Boyajian mentions this.

If one or two of the three circuits delivers power to a load to which constants R and X may be assigned, the terminal potential of the circuit may be replaced by $-I\,(R + j\,X)$; *e. g.*, in the case of a load on circuit (3) equation (4) may be written:

$$I_3\,(R + j\,X + r_3 + j\,x_{33})\,I_3 + j\,x_{13}\,I_1 + j\,x_{23}\,I_2 + E = 0$$

In this way it becomes a simple matter to determine the power currents in each of the windings of a three-circuit transformer.

Another even more interesting point is the operation of three-circuit transformers on three-phase circuits. In this case the third circuits of each transformer are usually connected in delta and spoken of as the tertiary delta. One of the principal reasons for this is to provide a sure path for the third harmonic exciting current if the other windings are both connected in Y. The tertiary Δ is also used to supply power, often at a relatively low voltage. The general method of analysis is as follows: Write the voltage equations similar to equations (2), (3) and (4) for each winding of each transformer, nine equations in all. Add the voltages across the three windings numbered (1) and divide by 3. By definition this is the zero-sequence voltage in the first winding[2]. This gives

$$V_{10} = (r_1 + j\,x_{11})\,I_{10} + j\,x_{12}\,I_{20} + j\,x_{13}\,I_{30} + E_0 \qquad (9)$$

This assumes that the three transformers are in all essential respects identical. The added subscript 0 signifies that the quantity is the zero-sequence component. Likewise, we may write

$$V_{20} = (r_2 + j\,x_{22})\,I_{20} + j\,x_{12}\,I_{10} + j\,x_{23}\,I_{30} + E_0 \qquad (10)$$

$$V_{30} = (r_3 + j\,x_{33})\,I_{30} + j\,x_{13}\,I_{10} + j\,x_{23}\,I_{20} + E_0 \qquad (11)$$

If the third windings form the tertiary delta, V_{30} is zero. This gives a useful relation for E_0 which may be substituted in the other equations (9) and (10). Making this substitution gives

$$V_{10} = (r_1 + j\,x_{11} - j\,x_{13})\;I_{10} + j\,(x_{12} - x_{23})\,I_{20} - (r_3 + j\,x_{33} - j\,x_{13})\,I_{30} \qquad (12)$$

and

$$V_{20} = (r_2 + j\,x_{22} - j\,x_{23})\,I_{20} + j\,(x_{12} - x_{13})\,I_{10} - (r_3 + j\,x_{33} - j\,x_{23})\,I_{30} \qquad (13)$$

We also have the general relation that

$$I_{10} + I_{20} + I_{30} = 0 \qquad (5)$$

Let us consider a few of the cases that may commonly arise.

1. Primaries and secondaries in Δ.

In this case $V_{10} = 0$ and $V_{20} = 0$, and the only values of the zero-sequence currents that will satisfy these conditions are zero. That is, there can be no zero-sequence load current in any of the windings under any condition even if it should exist in some unbalanced Δ-connected load, as it might. Or, it may be said that any current that may exist in either of the other deltas can only affect the current in the tertiary delta to a minor degree. That is, additional current in either delta will probably produce a small change in the terminal potentials of the tertiary windings and so alter the currents they may be delivering. Other than this the tertiary current is not affected. Indeed, as is well known, it is only when there is the possibility that the primary or secondary may carry zero-sequence currents that there can be produced any important modification of the tertiary currents, except, of course, as the load directly connected to the tertiary windings is changed.

2. Primaries in Δ, secondaries in Y with neutral grounded and with a current to ground of $3\,I_G$.

In this case the zero-sequence current in the secondary is I_G and from equation (5)

$$I_{10} + I_{30} = -I_G$$

Since the primaries are in Δ, $V_{10} = 0$ and we thus have

$$(r_1 + j\,x_{11} - j\,x_{13})\,I_{10} + j\,(x_{12} - x_{23})\,I_G - (r_3 + j\,x_{33} - j\,x_{13})\,I_{30} = 0$$

Eliminating I_{10} from three equations gives

$$I_{30} = -I_G \frac{Z_1}{Z_1 + Z_3}$$

For the meaning of Z_1 and Z_3 see equations (6,) (7), and (8) and the three following ones. That is, the total current to ground divides between the primary and tertiary as it would

2. Methods of Symmetrical Co-ordinates Applied to the Solution of Polyphase Networks. C. L. Fortescue, A. I. E. E., Transactions, 1918, Vol. XXXVII, p. 1027.

between two impedances Z_1 and Z_3 connected in parallel. There are also the positive- and negative-sequence currents. But they are equal and opposite in the primary and secondary just as if the tertiary were not present. The zero-sequence component in the secondary voltages is from (13)

$$V_{20} = \frac{Z_1 Z_2 + Z_2 Z_3 + Z_3 Z_1}{Z_1 + Z_3} I_{20}$$

For the meaning of these impedances see equations (6), (7) and (8) and the three following ones.

Another interesting point about this connection is that the third-harmonic component of the exciting current divides between the primary and tertiary but not in the same proportion as do the load currents. Since in this case the secondary can carry no third-harmonic exciting current,[3] it is without effect on its division between the primary and tertiary, and the impedances that are involved are the true leakages between these windings. The ratio of the third-harmonic components is:

$$\frac{I_3}{I_1} = \frac{r_1 + j\,3\,(x_{11} - x_{13})}{r_3 + j\,3\,(x_{33} - x_{13})}$$

In the first case, however, in which all of the windings are in Δ, the third-harmonic components of the exciting current will divide between all three windings inversely as their third-harmonic impedances. That is, the third-harmonic components divide as:

$$\frac{I_1}{r_1 + j\,3\,(x_{11} - x_{13} + x_{23} - x_{12})} = \frac{I_2}{r_2 + j\,3\,(x_{22} - x_{23} - x_{12} + x_{13})} = \frac{I_3}{r_3 + j\,3\,(x_{33} - x_{13} - x_{23} + x_{12})}$$

3. Primaries in Y, secondaries in Y with neutral grounded.

In this case the sum of the primary currents must be zero and I_{10} is thus equal to zero. From this I_{30} equals $-I_{20}$ which is one-third of the current to ground. Again there are also positive- and negative-sequence currents of the same magnitude which are equal and opposite in the primaries and secondaries but which do not exist in the tertiaries. In this case grounding the generator neutral has no effect on the current distribution since the generator is otherwise insulated from the secondaries. The displacement of the primary neutral, viz. V_{10}, is from equation (12)

$$V_{10} = I_{20} Z_3$$

The displacement of the secondary neutral is

$$V_{20} = I_{20} (Z_2 + Z_3)$$

4. Primaries in Y with neutral grounded; secondaries in Y with neutral grounded; generator neutral also grounded.

If there is no impedance between the generator and the primaries and the generator is balanced, the zero-sequence primary voltage is zero. That is $V_{10} = 0$. Thus we have: (see equation (12))

$$(r_1 + j\,x_{11} - j\,x_{13})\,I_{10} + j\,(x_{12} - x_{23})\,I_{20} - (r_3 + j\,x_{33} - j\,x_{13})\,I_{30} = 0$$

also

$$I_{10} + I_{20} + I_{30} = 0$$

But $I_{20} = I_G$ where $3\,I_G$ is the current to ground on the secondary side. Solving these relationships gives, as in case 2,

$$I_{30} = -I_G \frac{Z_1}{Z_1 + Z_3}$$

The displacement of the secondary neutral or the zero-sequence component of the secondary voltages is the same as in case 2 if there is no impedance between the generator and the primaries.

If there are equal line impedances of Z between the generator and the primaries and an impedance of Z_n between their neutrals the current in the tertiary is

$$I_{30} = -I_G \frac{Z_1 + Z + Z_n}{Z_1 + Z + Z_n + Z_3}$$

The general effect of this is to increase the tertiary current. If there is any unsymmetry in the lines between the generator and the primaries the solution is somewhat more difficult involving as it does the positive- and negative-sequence currents. For in this case a positive sequence load current will give zero-sequence line drop due to the negative-sequence component of the line impedance. Grounding the neutral of a Y-connected system has of itself no effect in determining whether or not there is a zero-sequence component in the Y voltages, for it is possible even with the neutral grounded that the sum of the Y-voltages should not be zero.

There are several interesting cases involving auto-transformers,[4] of which we will consider three. The fundamental equations are now in slightly different form. Refer to Fig. 6 herewith. All of the resistances and reactances will be given on the basis of a transformer which has the same number of turns in windings (1), (2) and (3). The voltages in the individual windings are given in equations (2), (3) and (4). The primary potential, V_{1n}, is however V_1 plus V_2 and is

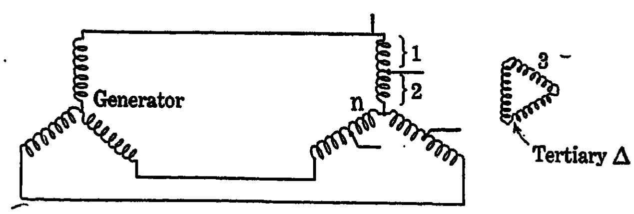

FIG. 6

$$V_{1n} = I_1 (r_1 + j\,x_{11} + j\,x_{12}) + I_2 (r_2 + j\,x_{22} + j\,x_{12}) + I_3 (j\,x_{13} + j\,x_{23}) + 2\,E$$

Eliminating E as before gives

$$V_{n0} = I_{10}(r_1 + j\,x_{11} + j\,x_{12} - j\,2\,x_{13}) + I_{20}(r_2 + j\,x_{22} + j\,x_{12} - j\,2\,x_{23}) - I_{30}\,(2\,r_3 + j\,2\,x_{33} - j\,x_{13} - j\,x_{23})$$

Substituting the relation that $I_{20} = -I_{10} - I_{30}$ we have

$$V_{n0} = I_{10}\,(Z_1 - Z_2) - I_{30}\,(Z_2 + 2\,Z_3)$$

If both the generator and transformers are grounded and there is no impedance between the generator and the transformers and the generator voltages are balanced, V_{n0}, equals zero, and

$$I_{30} = I_{10} \frac{(Z_1 - Z_2)}{Z_2 + 2\,Z_3}$$

Thus if the tertiary is symmetrically located with respect to both of the other windings of the auto-transformer and they themselves are symmetrically located with respect to the iron core the tertiary will carry no current since in this case Z_1 and Z_2 are equal. If, however, the generator is unbalanced or there is impedance between it and the transformer, the tertiary will carry current even though the windings are symmetrically located as described.

In case the generator is not grounded the zero-sequence current I_{10} is zero and I_{30} equals $-I_{20}$, that is, it is one-third the current flowing into the neutral of the transformers. The displacement of the transformer neutral in this case is

$$V_{n0} = I_{20}\,(Z_2 + 2\,Z_3)$$

If the generator is grounded but the neutral of the transformers

3. The secondary terminals are assumed to be free.

4. Performance of Auto-Transformers with Tertiary Windings under Short-Circuit Conditions. J. Mini, Jr., J. L. Moore, R. Wilkins. A.I. E.E. TRANSACTIONS 1923, page 1060.

is not grounded, the zero-sequence current in the tertiary must be equal and opposite to the zero-sequence current in the primary since $I_{20} = 0$. That is, it is one-third of the current to ground either at the generator or load. The displacement of the transformer neutral is now

$$V_{n0} = I_{10} (Z_1 + 2 Z_3)$$

The performance of the four-circuit and, in general, of the n-circuit transformer can be calculated by the same methods. When the transformer has more than three circuits little, if anything, is gained by attempting to represent it by an equivalent net work.

Using the same nomenclature as before we may write:

$$V_1 = I_1 (r_1 + j x_{11}) + j x_{12} I_2 + j x_{13} I_3 + j x_{14} I_4 + E \tag{14}$$

$$V_2 = I_2 (r_2 + j x_{22}) + j x_{12} I_1 + j x_{23} I_3 + j x_{24} I_4 + E \tag{15}$$

$$V_3 = I_3 (r_3 + j x_{33}) + j x_{13} I_1 + j x_{23} I_2 + j x_{34} I_4 + E \tag{16}$$

$$V_4 = I_4 (r_4 + j x_{44}) + j x_{14} I_2 + j x_{24} I_2 + j x_{34} I_3 + E \tag{17}$$

Also

$$I_1 + I_2 + I_3 + I_4 = 0 \tag{18}$$

These five fundamental equations may be handled by a variety of ways. Since there is some advantage in having them in symmetrical form we will use the following method of elimination. First eliminate E by taking successive differences. Then eliminate I_4 from the first difference, I_1 from the second difference, and I_2 from the third difference. These three equations together with equation (18) are sufficient to determine the currents in any case. If it is of any advantage, the loads on any of the windings may be replaced by their equivalent impedances, in which case the terminal voltages of these circuits will of course be taken as zero. We thus have:

$$V_1 - V_2 - I_1 [r_1 + j (x_{11} - x_{12} - x_{14} + x_{24})]$$
$$- I_2 [r_2 + j (x_{22} - x_{12} + x_{14} - x_{24})] + j (x_{13} - x_{23} + x_{24} - x_{14}) I_3 \tag{19}$$

$$V_2 - V_3 = I_2 [r_2 + j(x_{22} - x_{23} - x_{12} + x_{13})]$$
$$- I_3 [r_3 + j (x_{33} - x_{23} + x_{12} - x_{13})] + j(x_{13} - x_{34} + x_{24} - x_{12}) I_4 \tag{20}$$

$$V_3 - V_4 = I_3 [r_3 + j(x_{33} - x_{34} - x_{23} + x_{24})]$$
$$- I_4 [r_4 + j (x_{44} - x_{34} + x_{23} - x_{24})] + j (x_{24} - x_{14} + x_{13} - x_{23}) I_1 \tag{21}$$

and the relation that

$$I_1 + I_2 + I_3 + I_4 = 0 \tag{18}$$

An examination of these equations shows some interesting facts in regard to the impedances. In the first equation $r_1 + j (x_1 - x_{12} - x_{14} + x_{24})$ is the impedance that would be assigned to the first winding if the first, second and fourth windings were considered as a three-circuit transformer. We will represent this by Z_{124}. The impedance $r_2 + j (x_{22} - x_{12} - x_{14} - x_{24})$ is that which would be assigned to the second winding if the first, second and fourth were considered as a three-circuit transformer. We will represent this by Z_{214}. The first subscript shows to which winding the impedance is attached. The second and third subscripts indicate which of the other windings are grouped with the first to form a three-circuit transformer. The order of the second and third subscripts is unimportant; that is, there is no difference between Z_{124} and Z_{142}. It will also be noticed that the coefficient of I_3 in the equation (19) is $Z_{213} - Z_{214}$, that the coefficient of I_4 in equation (20) is $Z_{342} - Z_{312}$, and that the coefficient of I_1 in equation (21) is $Z_{413} - Z_{423}$. Thus the equations of differences may be written as follows:

$$V_1 - V_2 = I_1 Z_{124} - I_2 Z_{214} + I_3 (Z_{213} - Z_{214}) \tag{22}$$

$$V_2 - V_3 = I_2 Z_{231} - I_3 Z_{321} + I_4 (Z_{342} - Z_{312}) \tag{23}$$

$$V_3 - V_4 = I_3 Z_{342} - I_4 Z_{432} + I_1 (Z_{413} - Z_{423}) \tag{24}$$

There are some other interesting relations between these impedances.

For example,

$$Z_{124} - Z_{123} = - Z_{214} + Z_{213}$$
$$Z_{134} - Z_{132} = - Z_{314} + Z_{312}$$
$$Z_{421} - Z_{423} = - Z_{241} + Z_{243}$$

The values of these impedances can be determined by measurement if voltage is applied to one winding and *one* of the other windings is short-circuited. If, for example, Z_{12} is the leakage impedance of the first and second windings when neither of the others carry current, then it follows[3] that:

$$Z_{123} = \frac{Z_{12} + Z_{13} - Z_{23}}{2}$$

O. G. C. Dahl: I first want to discuss the paper by Mr. Boyajian. Mr. Boyajian states that the separate leakage reactance of one winding of a transformer is not a definite quantity. It seems to me, however, that before we make any attempt to determine whether leakage reactance is an explicit quantity or not, we ought to have an accepted definition of what we mean by the term leakage reactance. Leakage reactance of one winding with respect to another ought, in my opinion, to be the reactance caused by the part of the flux set up fully or partly in air by a current in the first winding which does not produce any linkages whatever with the second winding. I believe that on the basis of this definition, the separate leakage reactance of a winding is a perfectly definite quantity and does not in any manner depend upon the connections or the load conditions.

Of course, this reactance is not the reactance which should be assigned to a winding in a three- or four-circuit transformer when more than two of the windings carry current. The reactance of a winding in this case is a leakage reactance in the sense that it is caused by fluxes which do not exist exclusively in the core. These fluxes, however, are not entirely leakage fluxes according to the definition given above. They are partly mutual fluxes, and give rise to mutual reactances ("mutual leakage reactances") which enter as a part of the total or effective reactances. This idea, I think, is very clearly brought out in the discussion by Prof. Lyon.

Mr. Boyajian makes use of the classical representation of the two-circuit transformer and states that the splitting of the reactance into primary and secondary has no meaning unless the circuit representing excitation is considered. It should be noted that such a three-circuit network is not an *exact* representation of a two-circuit transformer, although it represents the transformer very closely.

Let us assume then that Fig. 3 in Mr. Boyajian's paper represents a two-circuit transformer. According to the classical theory the voltage across the excitation impedance (Z_3) should equal the voltage induced in the windings by the flux which exclusively exists in the core (usually called the mutual flux). If this is assumed and the network is analyzed on the three-circuit basis, it can be shown that the presence of the fictitious excitation circuit does not affect the distribution of reactance between primary and secondary. Considering the currents positive when flowing toward the common point, the equations for a three-circuit transformer are:

$$V_1 = (r_1 + j x_{11}) I_1 + j x_{12} I_2 + j x_{13} I_3 + E \tag{1}$$

$$V_2 = (r_2 + j x_{22}) I_2 + j x_{12} I_1 + j x_{23} I_3 + E \tag{2}$$

$$V_3 = (r_3 + j x_{33}) I_3 + j x_{13} I_1 + j x_{23} I_2 + E \tag{3}$$

$$I_1 + I_2 + I_3 = 0 \tag{4}$$

The reader is referred to Prof. Lyon's discussion for a complete explanation of the symbols. Equation (4) signifies that the exciting current is neglected in the three-circuit transformer, while for the two-circuit transformer it simply indicates that the sum of the primary and secondary currents equals the current required for excitation. When these equations apply to the two-circuit transformer, evidently $V_3 = 0$. Introducing this in equation (3), the following expressions may be obtained from the equations above:

$$V_1 = Z_1 I_1 - Z_3 I_3 = [r_1 + j (x_{11} - x_{13} + x_{23} - x_{12})] I_1$$
$$- [r_3 + j (x_{33} - x_{13} + x_{12} - x_{23})] I_3 \tag{5}$$

$$V_2 = Z_2 I_2 - Z_3 I_3 = [r_2 + j (x_{22} - x_{23} + x_{13} - x_{12})] I_2$$

$$- [r_3 + j (x_{33} - x_{23} + x_{12} - x_{13})] I_3 \quad (6)$$

which may be written

$$V_1 = Z_3 (I_1 + I_2) + Z_1 I_1 \quad (7)$$

$$V_2 = Z_3 (I_1 + I_2) + Z_2 I_2 \quad (8)$$

The term $Z_3 (I_1 + I_2)$ represents the voltage across the excitation circuit and shall be equal to the voltage (Ec) induced in the windings of the *two-circuit* transformer by the flux exclusively existing in the core. This voltage (Ec) is not the same as the voltage (E) induced in the windings of the three-circuit transformer, and the two should not be confused.

Equations (7) and (8) may now be written

$$V_1 = E\mathrm{c} + Z_1 I_1 = E\mathrm{c} + [R_1 + j (x_{11} - x_{12} + x_{23} - x_{13})] I_1 \quad (9)$$

$$V_2 = E\mathrm{c} + Z_2 I_2 = E\mathrm{c} + [R_2 + j (x_{22} - x_{12} + x_{13} - x_{23})] I_2 \quad (10)$$

These equations must be equivalent to equations (9) and (10) in my paper on *Separate Leakage Reactance of Transformer Windings*, namely,

$$V_1 = E_1\mathrm{c} + (R_1 + j x_{11}) I_1 + j x_{12} I_2 \quad (11)$$

$$V_2 = E_2\mathrm{c} + (R_2 + j x_{22}) I_2 + j x_{21} I_1 \quad (12)$$

From equations (9), (10), (11) and (12) we obtain

$$(x_{23} - x_{13}) (I_1 + I_2) = 0 \quad (13)$$

Since $I_1 + I_2$ is different from zero, being equal to the exciting current I_3, $x_{23} - x_{13}$ must be equal to zero. In other words we have $x_{13} = x_{23}$, which means that the mutual reactance ("mutual leakage reactance") between the fictitious excitation winding and the primary is the same as between the fictitious winding and the secondary, a result which appears entirely logical. By introducing this equality in the composite or effective reactances of the primary and secondary windings, we find that these reduce to the true leakage reactances given by my original definition. Hence, even in a two-circuit transformer the distribution of leakage reactance between primary and secondary is definite and is independent of whether or not a third circuit representing excitation is considered.

It is not improbable that the same idea might be extended to the three-circuit transformer which, when excitation is considered, represents a four-circuit problem. Also in this case it might be found that the presence of an excitation circuit does not affect the reactances to be assigned to the three actual windings. Of course, the reactances would still be *composite* reactances, the same as would be obtained for the three-circuit transformer when excitation is neglected.

Mr. Boyajian described four tests for experimental separation of the leakage reactances in a single, two-winding transformer. Theoretically these tests all appear valid, but no doubt when applied in practise the first two will give rise to considerable inaccuracies. This is mainly due to the presence of harmonics. It will, presumably, be preferable to use the fundamental component of the voltages and currents in question. Since these fundamental quantities in each case are associated with higher harmonics of considerable magnitude, it will be necessary to take oscillograms and to separate out the fundamental by analysis. Since, as mentioned, the order of magnitude of the harmonics, particularly the third, being large as compared to the fundamental components, this separation is difficult to perform with sufficient accuracy.

These tests were tried in our Research Laboratory. However, they did not yield good results at all for the reason mentioned above, although they were all performed on 1 : 1 ratio transformers. It seems to me, therefore, that the only way in which sufficient accuracy may be obtained is by making use of such connections as will separate out currents and voltages of one frequency. This is accomplished in tests No. 3 and No. 4 where the voltages and currents theoretically should be of impressed frequency. These tests, therefore, seem entirely rational when applied to transformers of unity ratio of transformation. When used with other ratios of transformation in connection with instrument transformers, the results may easily be subject to errors, as also pointed out by Mr. Boyajian. These tests will also fail to take into account the effect of saturation on the leakage reactance, if any. Personally, I think this effect is very small.

The three-phase, third-harmonic test seems to me to be the one to which the fewest objections may be raised. It determines the leakage reactances at normal (or any desired) saturation, and instrument transformers are not likely to affect the results seriously since their secondaries are connected directly to indicating meters. All doubt in regard to the calibration of the instrument transformers is thus eliminated. Of course, due to unbalance and other causes, it may be impracticable to obtain an entirely pure wave; but in any event the quantities of triple frequency which it is desired to measure will be entirely predominant and hence correct determination is highly facilitated even though oscillogram analysis may be necessary.

Mr. Boyajian's tests (1) and (2) make provisions for taking the effect of the exciting circuit into account, while his tests (3) and (4) eliminate any effect of the exciting current, because in each case the connections are such as to suppress the flux exclusively existing in the core. Since Mr. Boyajian is of the opinion that the exciting circuit affects the distribution of leakage reactance between primary and secondary, the two former tests should be expected to give results which differ from those obtained by the two latter tests. Mr. Boyajian does not mention this point at all, which to the writer seems quite important if it is assumed that the exciting circuit affects the distribution. Since, as shown, this is not the case, it would not make any difference in practise which test was employed as far as this particular point is concerned.

In connection with test No. 5 in which the Y-Δ-Δ connection is used, Mr. Boyajian presents a table giving the distribution of third-harmonic circulating current between the two closed deltas. His figures show that the distribution of this current, although to a comparatively small extent, depends upon the flux density in the core. Experiments performed in our Research Laboratory show less dependency on flux density. The table also indicates that the distribution of third-harmonic current between the two deltas to a certain extent depends on the reactance between the Y-connected winding and the two delta windings. There does not seem to be any reason why this reactance should enter into the problem at all. I am inclined to attribute the change in distribution to unbalance of the transformers rather than to any other cause. Even if the transformers are very well balanced and the ratio of transformation is uniform, it is practically impossible to avoid a small amount of fundamental in addition to the third harmonic in the closed delta circuits. According to Mr. Boyajian's sketch, Fig. 9, the third-harmonic currents were measured by inserting meters only in the closed windings. It is hardly safe to assume that the currents measured were of purely triple frequency unless this was checked by oscillograph.

Next, I want to say a few words in regard to Mr. Peters' discussion. Mr. Peters accuses me of saying that when the triple-frequency voltage, which appears when the third-harmonic current is fully suppressed, is divided by the triple-frequency leakage impedance, the triple-frequency current is obtained. I am surprised indeed that any of my statements can be interpreted in such a manner. I fully agree with Mr. Peters that the relation between the triple-frequency "open-circuit voltage" and the triple-frequency current does not follow Ohm's law. The relation, however, between the triple-frequency voltage, which is induced in the winding by the triple-frequency flux actually existing in the core, and the triple-frequency current, does follow Ohm's law.

It is well known that the third-harmonic voltage depends upon the third-harmonic current which flows. I briefly mentioned this in my paper on *Transformer Harmonics and Their Distribution* but did not discuss the mechanism of the interaction in detail. I stated, however, that it was my intention to do so in a

future paper. Since this particular question, however, is brought up, I would like to say that the effect of the third-harmonic current on the third-harmonic flux and corresponding voltage may very illustratively be compared to the effect of the armature reaction in a synchronous alternator. In the latter, the excitation voltage will exist between the terminals if the machine carries no load. As soon as load is applied to the machine, however, the voltage which is induced in the winding is changed due to the effect of armature reaction, and the excitation voltage becomes entirely fictitious. If the actually induced voltage is divided by the sum of the leakage impedance and the external impedance of the machine, we obtain the current which flows in the circuit. If the synchronous impedance corresponding to the particular flux density is known, then the same current may be obtained by dividing the fictitious excitation voltage by the sum of the synchronous impedance and the external impedance. What I have done for the transformer is equivalent to the former operation. If it were possible to ascertain the value of the transformer impedance which would correspond to the synchronous impedance in the rotating machine, then the triple-frequency current could be obtained by dividing the open-circuit third-harmonic voltage by the sum of this impedance and the external impedance, if any. Of course, the internal impedance to be used in this case would depend upon and vary with the flux density, and hence with the triple-frequency current. There is a possibility that an impedance of this sort may be determined on an empirical basis, and I have looked into that question to quite an extent. However, the work has not as yet proceeded far enough, and I am not ready at this time to make a definite statement.

I agree with Mr. Peters that it was unfortunate that the ammeter had to be shifted from one of the closed deltas to the other in the Y-Δ-Δ test for determination of third-harmonic current division. I called attention to this fact in the paper. It should be noted, however, that while the meter was changed the oscillograph shunts and vibrators, which constituted the main part of the resistance in the corners of the two deltas, were never short-circuited, but always left in the circuits even when the ammeter was removed. The resistance of the shunted vacuum thermocouple ammeter was 0.3 ohm when oscillograms Nos. 9, 10 and 13 were recorded, and 0.06 ohm when Nos. 11 and 12 were taken. Hence, the resistance of the measuring instrument was in all cases far from being of the order of magnitude of the total impedance of the winding, as Mr. Peters states. In the most unfavorable cases (oscillograms Nos. 10 and 11) the effect of a change in resistance of 0.3 ohm on the magnitude of the total impedance of the low-impedance delta winding is about 10 per cent.

I cannot give any definite reason for the discrepancy between the values of leakage impedance of winding No. 3 as determined by the two-winding and three-winding methods. As Mr. Peters points out, the one found by the latter ought to have been the smaller, since it was taken with respect to winding No. 2 instead of with respect to No. 3. I do not think, however, that the difference would have to be as large as 25 per cent, even though the distance between the coils is reduced by approximately this amount. Such a direct relation between spacing and leakage reactance would exist only with a very ideal distribution of leakage flux of uniform density, which does not obtain in an actual transformer.

The discrepancy may be due to the effect of unbalance or to inaccuracies in determining the reactances by the two-winding method, or both. In the two-winding tests the third-harmonic voltages which had to be measured, particularly at the lower densities, were very small and this fact may have affected the precision of the measurements.

I fully agree in the remarks made by Mr. McCurdy. The matter of whether a leakage reactance is definite depends upon definition, a point which I have tried to amplify in my discussion of Mr. Boyajian's paper. Of course, as Mr. McCurdy also states, the leakage impedance is not the impedance which should be assigned to a winding in all cases. It depends upon connections used and the number of circuits carrying current.

Prof. Lyon's discussion of applications to three- and four-circuit transformers is very interesting and illuminating. It brings out very clearly the difference between the leakage reactance of one winding with respect to some other winding, and the reactance which has to be assigned to the same winding in case three or more windings carry current of the same frequency.

Aram Boyajian: Professors Karapetoff, Lyon, and Dahl and Mr. Peters seem to be in agreement with the speaker on the main points of the paper. Thus Prof. Karapetoff says, "In a transformer with more than two secondaries, the indefiniteness of the division of the leakage fluxes among the individual windings lies in the very nature of the phenomenon." Prof. Lyon offers a number of equations because, he says, "it makes clearer some points that Mr. Boyajian brings up in his recent paper on the theory of such transformers." Prof. Dahl is no less explicit when he says (following his equation **11**), "The relative aspect of the leakage reactances should be carefully noted. The leakage reactance of a winding is not a quantity which is dependent upon and characteristic of that winding alone; it must, of necessity, be defined with respect to some other winding. This fact becomes particularly important in multi-winding transformers. Thus, in a transformer having three windings designated Nos. 1, 2 and 3, the leakage reactance of winding No. 1 with respect to winding No. 2 will be in general different from the leakage reactance of the same winding with respect to winding No. 3. . . "

Mr. Ferris' attitude is, I think, entirely reasonable. Without generalizing and dogmatizing beyond his immediate problem, he states that in dealing with third-harmonic troubles it would be very desirable to formulate some sort of individual leakage reactances which could be used in the computation of residuals and third-harmonic line currents. This probably can be done to some tolerable extent, subject of course to variation with changing degree of saturation. More investigation would be desirable in this direction.

Mr. McCurdy claims that the speaker "is in error in stating that the difficulties which have arisen in dividing leakage impedances between windings are due to any lack of definiteness of the problem." What I have claimed was that (a) a single resolution of universal application is impossible, not merely difficult, and (b), that resolutions for particular applications are easy, describing half-a-dozen methods for exciting-current applications. Mr. McCurdy's interest in the subject being confined exclusively to a very definite particular problem, *viz.*, third-harmonic telephone interference, *his* difficulty was not due to the indefiniteness of the general problem, even though the general problem is indefinite. His difficulty apparently lay in the belief that the third-harmonic method is the only possible method of resolution for exciting-current applications.

Ordinarily, we speak of two kinds of transformer reactance: (1) open-circuit or magnetizing reactance, (2) short-circuit or leakage reactance. Thus, leakage reactance is the reaction of the transformer to the load currents. Still, Mr. McCurdy wants to restrict the use of the term "individual leakage reactances" only to magnetizing-current applications by saying that "it leads to confusion to call such individual impedances of three-winding transformers 'individual leakage impedances'." If the impedance offered by a transformer winding to its load current may not be called its leakage impedance, I fail to see what else may be called leakage impedance. I have justified the use of the term "leakage impedance" in connection with exciting-current applications, only by considering the excitation kv-a. as a load in a fictitious auxiliary winding.

Relative to the third-harmonic tests mentioned by the author, Mr. McCurdy asks if the effect of meter impedances and extraneous harmonics were eliminated. So far as extraneous harmonics

are concerned, they were previously found to be absent by oscillographic records, and in these particular tests no oscillograms were taken. So far as meter impedances are concerned no corrections or eliminations were necessary. The test consisted in this: we had two independent windings A and B dividing between them the third-harmonic excitation of the transformer. We noted that with a certain voltage impressed on the transformer, A took more than half of the third-harmonic exciting current. Leaving all meter and connections absolutely unchanged, but increasing the voltage impressed on the transformer considerably, we observed that this time B took more than half of the third-harmonic current. This showed, regardless of meter impedances, that the division of the third-harmonic impedance between the two windings had changed in changing the impressed voltage of the transformer. The phenomenon is explainable qualitatively by a consideration of the return magnetic circuits of the two windings.

Mr. McCurdy admits that the various test methods which I have described are entirely feasible with one-to-one ratio transformers, but he overestimates the difficulties which instrument transformers would introduce, the difficulties which I have already mentioned in my paper. As against his opinion that "these methods do not have much practical importance" and that the third-harmonic method is the only way, we have Mr. Peters' opinion that "These methods are so simple and direct that chances of error are very remote." We also have Mr. Weller's statement that test methods No. 1 can be accurately reproduced, and that he has resolved experimentally the reactances of a number of potential transformers without the aid of third harmonics. Mr. Weller's results are the more significant in view of the fact that the resolution of the leakage reactances of potential transformers is much more difficult than that of power transformers.

I wish to emphasize here the inherent weakness in giving the third-harmonic method a privileged position in this resolution.

In the first place, we must recognize that third harmonics are not a necessary inherent and unavoidable accompaniment of transformer action such as resistance or reactance or magnetizing current, but they are purely incidental and even avoidable if one wishes to pay the price. Leakage reactance, on the other hand, is an inherent accompaniment of transformer action, and is primarily formulated for, and effective to, the normal-frequency currents regardless of the presence or absence of third-harmonic phenomena. Does it appear reasonable to imply that the normal-frequency performance characteristics of the leakage reactances of the various windings cannot be determined except through the aid of the non-essential incidental third harmonics? Let us assume an air-core transformer; it certainly will have a large magnetizing current and a large leakage reactance, but no third harmonics. Does the resolution of leakage reactance become indeterminate now on account of the absence of third harmonics? Or assume an iron-core transformer: are we to think that, when it is excited at such high densities as to generate considerable third harmonics, the windings show definite individual reactances to fundamental-frequency currents; and that, when the transformer is so underexcited as to yield inappreciable third harmonics, the windings will not show definite individual reactances? Or again we ask, is the effect of the division of leakage reactance upon the normal-frequency characteristics so insignificant that it cannot be detected or measured by normal-frequency phenomena? If so, the resolution would become largely a third-harmonic phenomenon indifferent to fundamental frequency, a conclusion which the third-harmonic champions would hardly admit. We should, I believe, admit that if the resolution does make a sensible difference to fundamental-frequency characteristics, then that difference ought to give us a line on the desired resolution.

Mr. Weller mentions the interesting case of ring-wound current transformers. These constitute the simplest case for theoretical analysis. In them, all leakage reactance belongs to the outer winding, subject to a small correction due to the thickness of the inner winding.

Mr. Weller and Mr. McCurdy are right in stating that the passing reference at the end of the paragraph numbered 2 in the text should be applied to a potential transformer, not to a current transformer.

Prof. Dahl, commenting on the classical equivalent-circuit diagram of a two-winding transformer as used in my paper, says that it is not an *exact* representation, although he is willing to tolerate it as an approximation. One would be led to infer from such a comment that Prof. Dahl's equations do not imply such a diagram and that the leakage reactances which he has formulated, and tried to determine, are not the leakage reactances shown in this diagram. As a matter of fact, this is exactly the diagram implied by the classical equations which Prof. Dahl has used, and the leakage impedances shown therein are the very impedances which he is trying to determine. The impedance links of the equivalent circuit are somewhat variable depending on the saturation of the core exactly as the self and mutual reactances used in his equations are variable with density.

This case is probably illustrative of other seeming differences between the two papers.

Prof. Dahl offers a definition of leakage reactance in the belief that by it individual reactance will become a single-valued quantity incapable of more than one interpretation. Thus, the leakage reactance of a winding is defined as the "reactance caused . . . by a current in the first winding which does not produce any leakages whatever with the second winding." Referring to the clause "caused by a current," we ask, caused by which current? Any current and every current? Or is it some particular kind of current such as exciting current or load current? If it is the latter, we then ask, which load current, the one occasioned by the load in winding X or that due to the load in winding Y? The burden of my paper was to show that the leakage reactance which a winding offers to an exciting current is different from that which it offers to a load current, similar to the fact that the total reactance which a transformer offers to exciting current is different from the total reactance which it offers to load currents, and that if the load can be applied at more than one point, the leakage reactance (for instance of the primary) is different for each different location of the load and of the secondary with respect to which the primary leakage is being considered. Thus, even the definition which Prof. Dahl offers does not necessarily make the general resolution a single-valued operation.

Prof. Dahl, like Mr. McCurdy, seems to wish to restrict the individual leakage reactances to currents considered as exciting currents. Such restriction, however, fails to reckon with the historical fact that the term "leakage reactance" is something that has always been applied exclusively to the reactance of a machine for its load current, not only in the case of transformers but also in the case of induction motors and synchronous machines. What linguistic or historical justification can there be now in trying to restrict the leakage reactances of windings to exciting current? In my treatment, the exciting current comes in as a particular kind of load, a load in an auxiliary fictitious winding, and thus takes its place alongside of other loads, coordinate with them and entitled to no unique privileges. The problem then becomes that of a three-winding or multi-winding transformer.

I am fully aware that, in contrast to the foregoing system of considering all currents as load currents, it is possible to construct an alternative system in which all currents including load currents are considered as magnetizing currents, and are thus given the same mathematical treatment as the no-load magnetizing current. The initial steps in this latter method are quite elementary, and, therefore, the first impulse of nearly everybody on first approaching the subject of three-winding transformers is to try to attack it by beginning with the familiar equations,

$$E_1 = I_1 X_1 + I_2 X_{12} + \ldots$$
$$E_2 = I_2 X_2 + I_1 X_{12} + \ldots$$

where the voltages are total voltages and the currents are the total currents in the corresponding windings, and X_1, X_2, etc., X_{12}, X_{13}, etc., are the total (magnetizing) self and mutual reactances respectively. This latter method, however, leads to great complexity and an unnecessarily burdensome system of equations, whereas, the consideration of the load currents as load currents and the reactances as leakage reactances leads to wonderful simplification of equations, even though at first it may be a little difficult to grasp the point of view. It is certain that any system dealing with multi-winding transformers and starting with total currents and magnetizing self and mutual reactances must at some stage convert into load currents and leakage reactances, to be of any practical use. All this can be accomplished directly and with very little labor and mathematics once the comprehensive physical point of view is appreciated. The work done by Mr. Peters and the writer on the theory of three-winding transformers, as well as references in American and European technical literature that have come to my attention, seem to confirm this conclusion. Judging from very old treatises on transformers, the pioneers in transformer theory used to calculate load characteristics by the aid of self inductances and mutual inductances. Later it was discovered that the idea of leakage or short-circuit reactance introduces a wonderful simplification and precision into calculations by eliminating the need of any reference to the awkward magnetizing self and mutual inductances. It appears to me, therefore, that in dealing with load-current problems, to use magnetizing self- and mutual-reactance conceptions instead of leakage-reactance conceptions, is somewhat like using the instantaneous values of currents instead of their effective values. The question here is not which is correct (because both are correct), but which is more comprehensive? Which is more practical? Which utilizes to a greater extent the accumulated technical experience of the profession? Wouldn't we handicap ourselves unnecessarily if in every problem we should start with Maxwell's fundamental equations?

The conclusion which Prof. Dahl draws from the 13 equations in his discussion is that the reactances of the three branches of the equivalent circuit are definite quantities. This conclusion hardly needs a proof, but only the caution that this resolution refers to the exciting current because the various impedances used in the equations are the magnetizing impedances. Prof. Dahl further wishes to conclude that the resolution is independent of whether or not a fictitious excitation winding is assumed. However, whether or not a fictitious excitation-load circuit representing the kv-a. loss in the iron is expressly assumed, one is implied. For instance, if Z_1 is given as the self-inductive impedance of winding No. 1, it represents the leakage impedance between winding No. 1 and the excitation-load winding which we have postulated as hidden in the core to represent the excitation loss (kv-a., not only kw.) in the iron. Although I have called this a fictitious circuit, it is not altogether fictitious, because the core does constitute many little circuits and these may be represented by a single equivalent winding. The position and shape of this equivalent winding may not be arbitrarily assumed. It has to be such as to agree with the characteristics of each particular core.

Referring to the test methods described in my paper, Prof. Dahl states that some of them were tried out with one-to-one ratio transformers and found unsatisfactory due to the influence of the harmonics of the exciting current. It is very unfortunate that Prof. Dahl does not given any data at all, neither does he state just why the tests were considered unsatisfactory. It is possible that these tests were made after the publication of these papers and the data have not as yet been put into suitable shape for presentation. It is also possible that these tests at fundamental frequency did not check the previous third-harmonic tests and were therefore considered unsatisfactory. Now, so far as the effect of harmonics of exciting current on these tests is concerned, I think we can decide the matter rather definitely on theoretical grounds as follows:

The resolution of the normal-frequency leakage reactance by the aid of the third-harmonic test is based on the assumption that the same resolution holds at triple-frequency as at fundamental-frequency or at any other frequency. Now, if this assumption is true, that is, if all harmonics require the same resolution so that the ratio of the individual leakage reactances of the two windings is the same for all of the harmonics, then the division of the various harmonics of current between two windings ought to be the same whether one harmonic is tested or the other or whether their composite is tested, assuming that the meter impedances are not influencing the circuit conditions to any serious extent. Harmonics of exciting current could disturb the results only when the resolution of leakage reactance is different for different harmonics, and this I do not think Prof. Dahl would concede, because it would undermine the applicability of third-harmonic test results to fundamental-frequency phenomena. Furthermore, the resolution may be tested at various flux densities in the core, starting with very low densities to which harmonics are practically absent, and plotting a curve of resolution against flux density. This may then be compared instructively with the resolutions obtained by a single harmonic at the corresponding densities.

It is to be hoped that Prof. Dahl will investigate these various test methods thoroughly and that he will present his data to the Institute in another paper soon.

The curves presented by Mr. Palueff are interesting and have evidently been prepared with much care. It must be noted that he is dealing with the composite or resultant of two fluxes (produced by the magnetizing and load currents) and, therefore, the various voltages measured by the exploring coil are not directly indicative of individual reactances. Of course, so far as the individual leakage reactances (with respect to exciting current) of a transformer consisting of two circles in space are concerned, they can be very easily solved in accordance with equations (10) and (11) of my paper without having to plot any curve. It is unfortunate tht Mr. Palueff did not segregate the two components of fluxes and voltages.

Professor Karapetoff as an educator is rightfully somewhat concerned over the sense of uncertainty and indefiniteness that people may get if told of the relativity of the resolution of leakage reactance. It was attempted to guard against this opposite extreme by tabulating at the end of my paper a number of definite conclusions indicating specific applications and interpretations.

A New Two-Phase to Six-Phase Transformer

Connection of One Hundred Per cent Apparatus Economy

BY A. BOYAJIAN[1]

Member, A. I. E. E.

Synopsis.—A new transformer connection of 100 per cent apparatus economy is described for transformation from two-phase to six-phase and vice versa. Its merits from various standpoints are compared with those of the Scott and the Woodbridge connections.

Introduction

THIS paper describes a new two-phase to six-phase transformer connection which has an "apparatus economy" of one hundred per cent.

By apparatus economy is meant the ratio of the single-phase transformer kv-a. rating of the device to its kv-a. rating as a phase transformer. This ratio is sometimes called "internal power factor". This latter term, however, is not so good, because of the fact that, although at unity power factor loads the value of the internal power factor is identically the same as the apparatus economy, yet the internal power factor varies with the load power factor, while the apparatus economy is independent of the load power factor.

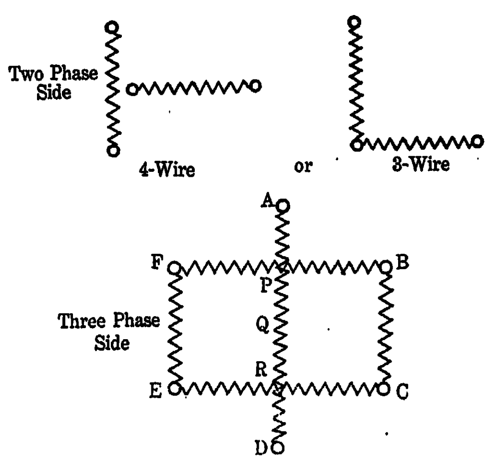

Fig. 1—Two-Phase to Diametric Three-Phase or Six-Phase Transformers

Three-phase side:

Voltages: *AD—BE—CF*—100 per cent

AP—PQ—QR—RD—25 per cent

BC—PR—FE—50 per cent

BP—PF—CR—RE—43.3 per cent

Currents in Lines—100 per cent

Current in *AP—PQ—QR—RD*—100 per cent

" " *BC—FE*—50 per cent

" " *BP—PF—CR—RE*—86.6 per cent

Description of the Connection

Fig. 1 shows the connection diagrammatically.

The core and flux are two-phase, so that two single-phase cores or one two-phase core would be necessary and sufficient.

Considering the windings, two windings are needed on the two-phase side, one for each phase. They may be interconnected (as *T*, *L*, or diametrically), or they may be entirely independent. This freedom is advantageous in being adaptable to any two-phase system.

On the six-phase side, we have a rectangle, *B C E F*, crossed by the line *A D*. The voltages of the various parts are shown in the illustration.

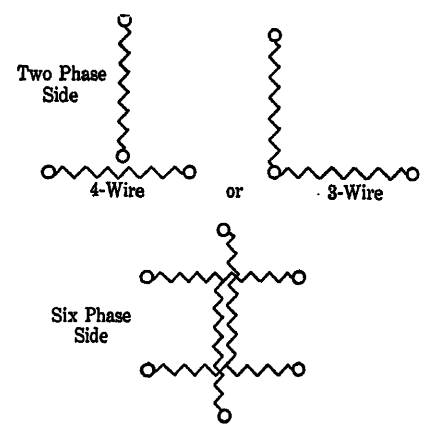

Fig. 2—Double-T or Double-Scott Connection

It may be noted that the six-phase side may be also considered a diametric three-phase system, since any diametric three-phase device may be operated from it.

New Connection Compared with the Double-T Connection

The common connection for two-phase to six-phase transformation is the so-called double-T or double-Scott connection shown in Fig. 2. While structurally there is a great deal of resemblance between this and the new connection, what little difference there is accounts for the difference in the apparatus economy of the two connections. The maximum apparatus economy which the Scott connection is capable of is 96.6 per cent (using non-interchangeable units and properly interlaced three-phase main windings) as against the 100 per cent apparatus economy of the new connection. Besides this difference in economy, the new connection is free from the trouble of the interlacing requirement for the two halves of the main winding in the Scott connection. This advantage is more appreciated if it is considered that six-phase circuits are usually of low voltage and high current, and proper interlacing of the two halves of the main is not a simple matter.

1. Of the General Electric Company, Pittsfield, Mass.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, N. Y., June 22-27, 1925.

It will be observed that the Scott connection can be converted into the new connection by redistributing the two teaser windings around the two main windings in accordance with Fig. 1.

A disadvantage of the new connection in comparison with the Scott connection is that the former is not adaptable for the use of interchangeable units. If a spare is needed, it must be a complete polyphase unit, while in Scott connection a single-phase spare may be sufficient. In this interchangeable scheme, however, the apparatus economy of the Scott connection is at best only 93.8 per cent.

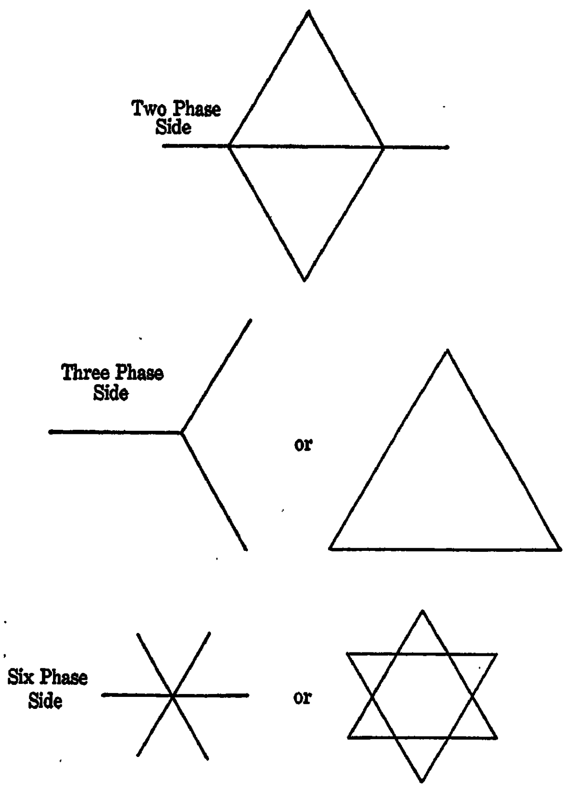

FIG. 3—THE WOODBRIDGE CONNECTION

NEW CONNECTION COMPARED WITH THE WOODBRIDGE CONNECTION

The Woodbridge connection is a 100 per cent economy connection shown in Fig. 3. Originally this connection was intended for two-phase to three-phase transformation, but its applicability to two-phase to six-phase transformation is obvious. The Woodbridge connection, although of high economy, is seldom used on account of three limitations: (1) being a 4-wire two-phase connection, it is not adaptable to 3-wire two-phase circuits; (2) the two-phase side is unsuited for taps; and (3) it is as complicated for two-phase to three-phase service as for two-phase to six-phase service, while in the matter of simplicity, adaptability and convenience for two-phase three-phase service the Scott connection is far ahead of any of the other many connections so far invented. The new connection here described is not adaptable at all to three-wire, three-phase service.

For six-phase service, the Scott, the Woodbridge and the new connections are of the same order of complexity in the matter of windings, but the latter two do not need the particular interlacing required by the Scott connection. Since taps are or would be placed on the two-phase side, in this service the Woodbridge connection is at a very serious disadvantage.

A point of great theoretical interest in this comparison is that both of the two 100 per cent economy connections are "diametric" in their derived phases, but free and flexible in their original. The Woodbridge connection uses three-phase flux, and is flexible in its three-phase side, its original side, being capable of either diametric or mesh connection. However, on its derived side,—viz., the two-phase side,—the connection is entirely limited to four-wire diametric connection. The new connection here described utilizes two-phase flux, and this being its original phase, it is capable of any two-phase connection. However, on its derived side, the three-phase side, it has to be diametric, that is, six-wire three-phase, and is therefore not adaptable to ordinary three-wire three-phase circuits.

Discussion

Vladimir Karapetoff: A general solution of two-phase to six-phase transformation is shown in Fig. 1 presented with this discussion. $O\,a$, $O\,b$, $O\,c$, $O\,d$, $O\,f$, $O\,g$, are six "star" voltages desired to be had on the six-phase side. As a simplest case,

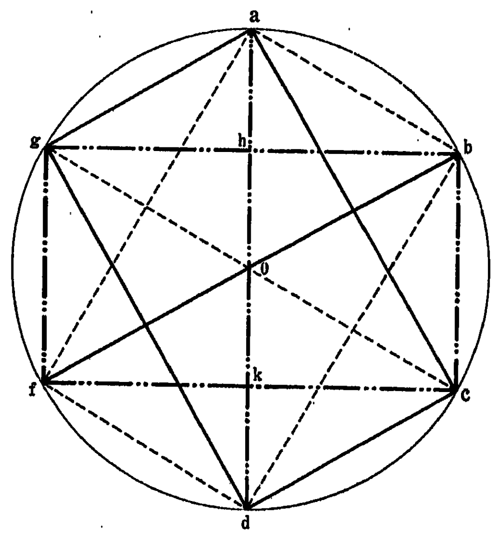

FIG. 1

imagine a six-phase synchronous motor adjusted to run at unity power factor and used as a load on a two-phase line. Then the foregoing six voltages may be considered, as those across the individual armature phases (star connected) of the motor. The problem of phase transformation consists in connecting the vertices of the hexagon by lines of two mutually perpendicular directions. Starting with point a, there are only three possible independent beginnings, viz., $a\,b$, $a\,c$, and $a\,d$. Beginning with $a\,b$, we have to draw $a\,b$, $g\,c$, $f\,d$, for phase I, and $a\,f$, $b\,d$, for phase II. This will give the figure drawn by dotted lines and

identical with that shown in Boyajian's Fig. 1.[1] Beginning with $a\ c$ gives again a Φ figure shown in full lines. Beginning with $a\ d$ gives an identical Φ figure drawn in "dash and dot." Thus, the Φ transformation is not one of several possible transformations, but the only possible *perfect* transformation.

By a perfect transformation I understand one in which only the vertices of the hexagon are used. With the double-T transformation, auxiliary points, h and k are necessary, and this causes reactive currents, increased kv-a. rating of the transformers, necessity for interlacing, etc. It will be seen from my Fig. 1 that no more lines interconnecting the vertices in a "perfect" way can be drawn; therefore, all possible solutions are included in this figure.

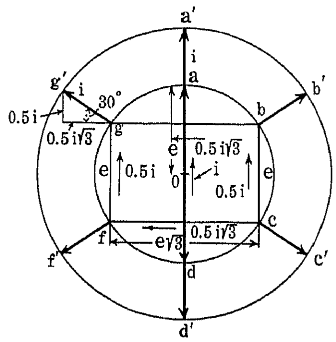

Fig. 2

For example, the six-pointed star shown in Boyajian's Fig. 3 may be readily seen in my Fig. 1. It may be of interest to point out that a sketch identical with Fig. 1 was included in the first edition of my "Experimental Electrical Engineering" published in 1909, and the general method of obtaining perfect phase transformations explained. However, I did not follow the matter any farther and did not realize that I had the Φ figure until I saw it in the paper under discussion.

The reason for which a perfect transformation gives 100 per kv-a. efficiency may be seen in Fig. 2. The six line currents flowing into the load are shown by the vectors $a\ a'$, $b\ b'$, etc. The six star voltages are in phase with these currents. Only two voltages, $O\ a$ and $O\ d$, are shown. Phase I of the transformer furnishes the currents $a\ a'$ and $d\ d'$ directly, and the kv-a. delivered is $2\,ie$. The current $g\ g'$ is furnished by both phases. Phase I supplies 0.51 and phase II supplies $0.5\ 1\ \sqrt{3}$. Thus the phase I furnishes altogether

$$2\,i\,e + 2\,(0.5\,i)\,e = 3\,i\,e.$$

Phase II furnishes

$$2 \times (0.51\sqrt{3}) \times (e\sqrt{3}) = 3\,i\,e.$$

In other words, both phases furnish equal kv-a., and all the currents in the transformer windings are in phase with the respective voltages. This means 100 per cent apparatus efficiency.

1. I suggest calling this kind of transformer connection the "Φ connection," because of some resemblance of the diagram to this Greek letter.

It will be seen that the Φ connection involves two "stub ends," a and d, and four "junction points," b, c, f, g, where two transformer windings are joined together. For a "perfect" transformation, the stub ends should be used only where the induced voltages in both systems are in phase with each other. At all other points, junctions should be used in order to produce a resultant current out of two components, each of which is in phase with its induced voltage for that particular transformer case.

It is shown in Fig. 3 herewith the usual T connection does not satisfy this condition, and for this reason its kv-a. efficiency is less than 100 per cent. Stub ends, a and b, are used in the phases in which the induced voltages differ by 30 deg. As a result, the three-phase currents $a\ a'$ and $b\ b'$ are out of phase with the induced voltages when the two-phase side is loaded at 100 per cent power factor. This causes unbalanced magnetomotive forces, increased magnetic leakage, and necessity for interlacing.

Aram Boyajian: Professor Karapetoff has proven for us that the transformer connection here described is the only possible two-phase-six-phase connection of 100 per cent apparatus economy utilizing two-phase fluxes and voltages. If his argument is true, as it appears to be, he saves us from futile effort at further invention along this line.

The connection here described originated in an effort to devise a two-phase-three-phase connection that would be free from the complications and limitations of the Woodbridge connection. Since the Woodbridge connection was based on three-phase flux and voltages, the solution of the problem was sought in the use of

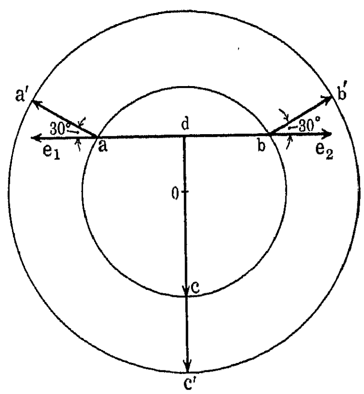

Fig. 3

two-phase flux and voltages. However, the three-phase system so derived turned out to be a diametric (that is, six-wire) three-phase system, unadaptable to three-wire three-phase systems, and was equivalent to a six-phase system. As stated in the paper, it appears to the author that this is inherent in the nature of things, that is, the derived system has to be diametric, such as four-wire two-phase, or six-wire three-phase. Maybe Professor Karapetoff can definitely prove this to us some time.

Losses in Iron Under the Action of Superposed Alternating- and Direct-Current Excitations

Synopsis:—*The paper presents the results of wattmeter measurements of iron loss in a small experimental reactor designed for a-c. and d-c. excitations. All the resistances were measured by the d-c. voltmeter-ammeter method, and the $I^2 R$ losses were subtracted from the total wattmeter readings. A-c. core losses are plotted against d-c. excitation for various a-c. flux densities. These curves were checked qualitatively by means of hysteresis loops taken with a special bilateral oscillograph.*

All results show a comparatively small change in core loss as d-c. excitation is added, the core loss even showing a decrease when the a-c. saturation is high.

The core loss proper is distinguished from the double frequency circulating current copper loss, and means are given for decreasing this $I^2 R$ loss.

* * * * *

Introduction

In thesis work at Massachusetts Institute of Technology in 1924, the authors investigated the losses in iron under the action of superposed alternating- and direct-current excitations, and the results of this investigation are given herewith. This paper was prepared while the authors were connected with that Institute.

The question of superposed excitation is one of wide interest in electrical engineering as it occurs in one form or another in many electrical machines. Perhaps the best known example is the d-c. saturated regulator and reactor. Some rectifier circuits have transformers that are partially saturated with direct current, and the question of iron loss may be very important in connection with the proposed high-voltage, d-c. transmission. Practically all rotating machinery is subject to magnetization at two or more frequencies at the same time, especially in the teeth and pole tips. Telephone and telegraph circuits also carry both direct and alternating currents in many cases.

Previous investigators in this field have found, in the main, a very decided increase in a-c. iron loss with an increase in d-c. bias, sometimes amounting to fifteen or twenty times the usual core loss. Only a few reports show any decrease in the iron loss. In most of those which show excessive losses, the circulating double frequency current which appears in the d-c. circuit or in some other winding on the core when direct-current excitation is added, has either been neglected or there have been other possible errors in the method of measuring the core losses.

They all agree, however, that the classical formula of Steinmetz expressing hysteresis loss does not hold at high-flux densities. Ball and others have attempted to fit the Steinmetz equation to the case of superposed fluxes by changing the value of the exponent and using some value of B which is a function of both the a-c. and d-c. flux densities. Although the authors cannot, at the present time, propose an exact formula, they believe that the hysteresis loss actually begins to decrease at very high d-c. flux densities, and finally becomes zero when the total change in flux caused by the a-c. component takes place above the saturation point of the iron.

The eddy-current component of core loss depends upon the a-c. flux change and not upon the d-c. component, and if the a-c. flux wave remains sinusoidal, the eddy-current losses should not change with an increase of d-c. excitation. As a matter of fact, the wave forms do become somewhat distorted, and the eddy-current loss probably goes up somewhat when direct current is added.

The authors found that total core losses remain practically constant for a given a-c. flux density, regardless of the amount of d-c. flux in the iron, though some change did occur at high and low a-c. flux densities. The losses increased when d-c. excitation was added if the a-c. saturation was low, and decreased if high. The loss curves were taken from wattmeter readings and were checked by dynamic hysteresis loops taken with a bilateral oscillograph. A study of the accuracy of this oscillograph was also made and they believe the loops shown are substantially correct.

Method of Test

The method consisted of measuring the total input to an iron-core reactor by a low power factor wattmeter and subtracting the $I^2 R$ losses in the windings, leaving the difference as the core loss of the reactor. Two circuits were used. One had the direct current and alternating current in series in the same coil, forcing all of the $I^2 R$ loss into this one coil where it could be easily measured; the other had three coils, two carrying direct current and the third alternating current alone. The latter had the advantage of better wave form but still brought the second harmonic current into one winding where it could be measured.

The series circuit is shown in Fig. 1. A storage battery supplied the direct current and a series resist-

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

ance regulated its value. Dynamometer ammeters were used to measure the current. A transformer kept the direct current out of the alternator windings. All voltage and frequency regulations were made with the field controls of the 5-kw. motor-generator set. The core under investigation weighed 20 lb. It was built up of 25-gage (0.022-in.) U. S. electric sheet with lap-joints. The outside dimensions of the core were 9 by 9 by 2 in. The cross-section of the middle leg was 2 by 2 in. while that of the rest of the core was 1 by 2 in. This gave 4 sq. in. for the a-c. flux path and 2 sq. in. for the d-c. flux when the three-coil circuit was used.

In taking readings, it was found necessary to measure the resistance at every point because of the effect of temperature changes while taking data. This was done

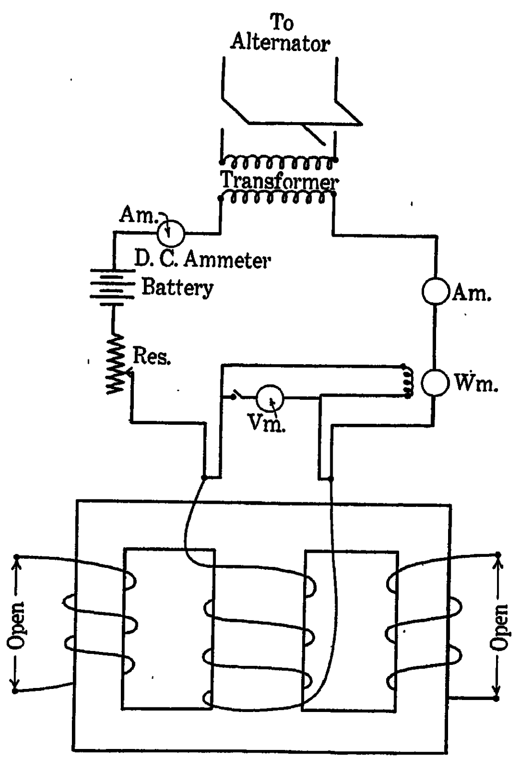

Fig. 1—Series Connection Showing Positions of Instruments

by the voltmeter-ammeter method using double-pole, double-throw switches to put the direct current alone in the windings. Carefully calibrated d-c. instruments were used, as the resistance had to be known with great accuracy in order to make the "subtraction method" at all reliable. With this arrangement, however, no difficulty was found in checking readings at different temperatures.

Fig. 2 shows a set of curves of core loss at various flux densities taken with the series circuit. The densities marked on the curves were figured from the applied voltage, and sine waves were assumed. If corrected for wave form and $I\,R$ drop, the values would be slightly lower than those indicated.

Since these curves did not agree at all with some similar curves taken at Massachusetts Institute of Technology in 1923, or with the results of other investigators, an attempt was made to discover the discrepancies. The circuit used in the M. I. T. report of 1923 is shown in Fig. 3. On considering this circuit, it was found that an alternating current of double frequency must flow in the direct current circuit, even though the

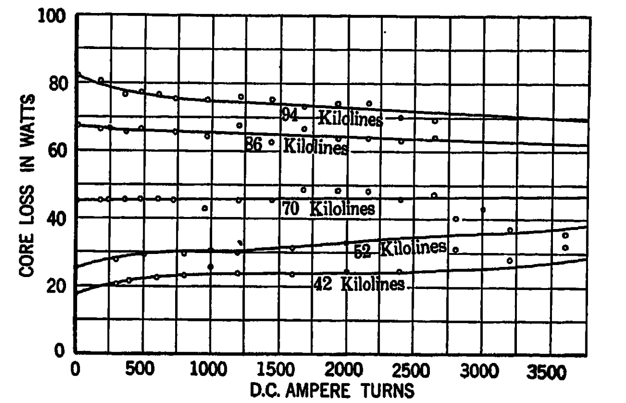

Fig. 2—Core Loss Curves for Various A-C. Flux Densities Plotted Against D-C. Ampere-Turns. Alternating and Direct Currents in Series in the Same Winding.

d-c. coils were balanced with respect to the fundamental when no current was flowing in them. If the direction of the winding is such that the a-c. voltages in the d-c. coils buck, it will be found that the a-c. flux will be *with* the d-c. flux in one core and *against* it in the other. This means that there will be a greater change of flux in one

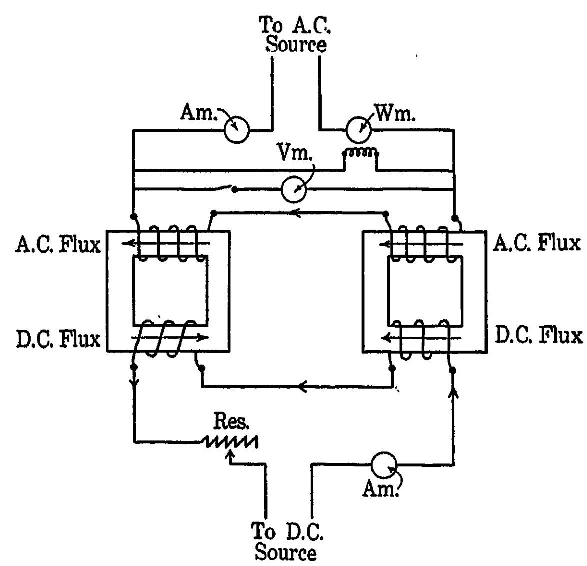

Fig. 3—Connection used in taking Curves of Fig.

core than in the other, due to the shape of the magnetization curve of iron, and hence more voltage will be induced in one coil than in the other at a given instant. This will produce a circulating current of double frequency. In fact, this is almost the identical circuit used at the Sayville Radio Station as a frequency doubler, and was first developed by Count von Arco.

When this circuit was duplicated with the identical reactors used in the work of 1923 but with an ammeter in the direct-current side that would read the square root of the sum of the squares of the r. m .s. alternating current and the direct current, and when the $I^2 R$ loss due to the circulating current was subtracted, the core loss checked that found by the simpler series circuit. At the a-c. flux density used it decreased slightly as direct current was added.

There was one peculiarity that is shown by Fig. 4. The upper line is the curve of "core loss" given in the

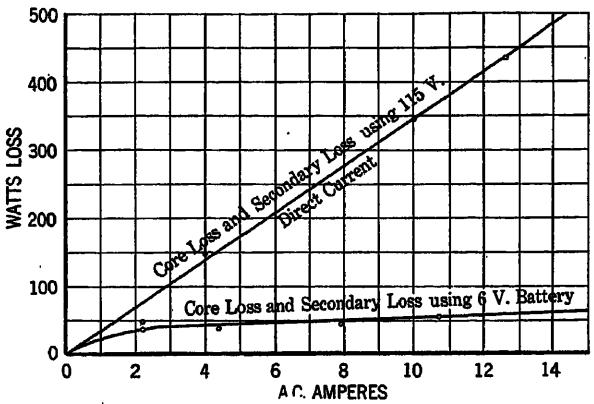

Fig. 4—Curves Showing Effect of Resistance in D-C. Circuit on Loss Due to Double Frequency Circulating Current

previous report, which really included the circulating current loss in the d-c. circuit; the lower curve is the *same thing* as read by our wattmeter. The true core loss lies under the lower curve. An explanation of the large difference is found in the different constants of the d-c. circuits. The upper curve was taken using direct current from the d-c. mains at 115 volts—a large resistance was necessary to cut it down to a value required for the windings on the reactors. In the lower curve, direct current was supplied from a storage battery of only a few cells, and a very small resistance was needed to regulate the current. In this case the second harmonic path was practically a short circuit, while in the first case it had a large resistance load in it.

It was discovered that as the resistance of the d-c. circuit was varied and the direct current kept constant by varying the voltage at its source, the circulating double frequency current remained substantially constant and approximately equal to $I_{dc}/\sqrt{2}$. This led to the suggestion that a short-circuited winding be provided in parallel with the d-c. winding in which this current could flow. This was tried and the total losses were still further decreased. The loss due to this current can be made about the same value as the iron loss without using an excessive amount of copper in this short-circuited coil. Since the r. m. s. value of the circulating current is $I_{dc}/\sqrt{2}$, if no parallel short-circuited coil is provided for the circulating current, the loss due to it will be equal to one-half the direct-current $I^2 R$ loss in the entire d-c. circuit, including the source of supply. It should be noted that any short-circuited winding should be placed next to the core in order to be most effective, as its leakage reactance will be less than if placed outside the d-c. coil.

The three-coil circuit mentioned here is shown in Fig. 5. This scheme has the disadvantage of having no d-c. flux in the middle leg of the core and consequently this flux is not so effective in changing the reactance as it might be, but the wave-form of the current is much improved by this form of core. Some core-loss curves were taken with this circuit and found to be substantially the same as those of Fig. 2, except for small differences due to the unsaturated portion of iron in the middle leg, and the increased reluctance of the direct current path. This was about three times as high as when the direct current was in series with the

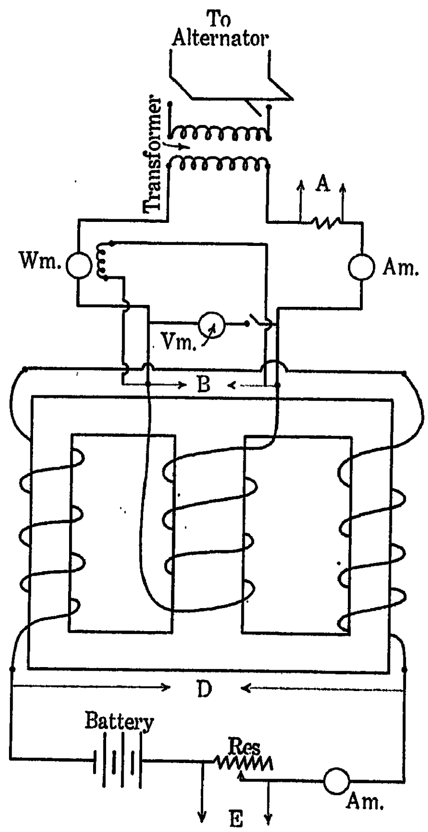

Fig. 5—Three-Coil Circuit Which Gives Better Wave Form Than the Series Circuit of Fig. 1 But Same Iron Loss

alternating current, as the area of the path was less and the length greater.

Families of curves taken at different frequencies are very similar to those shown in Fig. 2 except that they move up as the frequency is increased, much as they would if no direct current were present. The middle or straight curve comes at a higher a-c. flux density as the frequency goes up, although its actual position, the authors believe, would depend upon the relative amounts of hysteresis and eddy-current loss in the given core.

Oscillograms

Several oscillograms of the current and voltage in both the series and three-coil circuits were taken when the d-c. ampere-turns were of different values. The single-coil connection of Fig. 1 will be considered first. The addition of direct current caused the voltage wave to become quite peaked. This was due in part to the effects of the direct current on the supply transformer, as it had to circulate through the secondary of this transformer as well as through the reactor being tested. The volt-ampere load on the transformer was about half its rating when the largest value of direct current was used. The $I R$ drop across the regulating resistance also distorted this wave. The combined effects resulted in a flat flux wave, which in itself, would tend to cause less iron loss. That this was not the entire cause of decreased iron losses, however, will be apparent from the results of the other circuit.

The current wave with no direct current is the usual magnetizing current of iron with a high percentage of the third harmonic and other higher harmonics. When direct current is superposed, the lower half of the wave is cut off, more or less completely, depending upon the direct current value. Fig. 6 shows the voltage and current as well as the direct current alone before the alternator switch was closed. This peculiar current wave is due to the various harmonics which it contains. About 30 per cent each of a third and second harmonic, together with several higher ones, will account for this shape.

Fig. 6—Current and Voltage of the Series Circuit of Fig. 1 When Direct Current was Flowing. The D-C. Value is Shown by the Upper Horizontal Line, which Was Taken Before Closing the A-C. Switch

To make sure that there was not also some valve action in the storage battery that prevented the current wave from reversing at the a-c. frequency, a battery was put in series with an alternator giving the same r. m. s. voltage as the battery, and an oscillogram taken of the current and voltage waves. The current remained sinusoidal but was displaced above the zero axis. This displaced current changed sign without any indication of a valve action, although the lower peaks of the wave just barely extended across the zero line.

Fig. 7 shows the current and applied voltage of the three-coil circuit of Fig. 5 when the a-c. flux density was about 94 kilolines, and 4000 d-c. ampere-turns were in the outer legs. There is no distortion of the voltage wave as when the direct current was in series. There is also a decided improvement in the wave form of the current, because the iron was saturated by the direct current and was operated upon the straight-line portion of its magnetization curve. Since there are two possible paths through the iron for the a-c. flux in this arrangement, the current wave remains symmetrical. The third harmonic still remaining is due partly to the unsaturated portion of iron in the middle leg, and partly to the incomplete d-c. saturation of the outside legs.

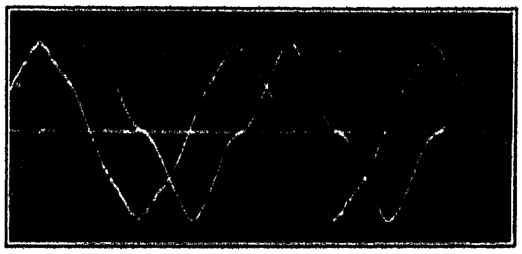

Fig. 7—Current and Voltage of the Three-Coil Circuit of Fig. 5 when 4000 D-C. Ampere-Turns Were in the Outer Legs of the Core

Fig. 8 shows the current and voltage in the d-c. circuit, and the a-c. voltage applied to the middle leg. The circulating current is of just double frequency and is practically free from other harmonics.

These oscillograms are typical of the thirty or more that were taken under different conditions, and show what wave forms may be expected from a saturated core reactor.

Fig. 8—Exciting Voltage (with Tooth Ripple) and Double-Frequency Circulating Current and Voltage in the D-C. Circuit. The Upper Horizontal Line is the Direct Current before the A-C. Switch was Closed, and the Double-Frequency Current is Symmetrical about this Current as an Axis

Hysteresis Loops

Dynamic hysteresis loops were taken with a two-dimensional oscillograph constructed at M. I. T. by T. W. Kenyon, and they check the wattmeter readings of core loss, at least qualitatively. There is a description of such an oscillograph by E. L. Bowles in the Journal of the A. I. E. E. for August, 1923. The instrument consists of two ordinary vibrators mounted

with their axes at right angles and the light beam is reflected by both mirrors, one giving it motion in one plane and the other deflecting it in a plane at 90 deg. to the first. One vibrator carries a shunted portion of the magnetizing current, and the other, a current which is proportional to the flux in the core. This current is obtained by inserting a very large inductance in series with an exploring coil on the core, and if the ratio of $\frac{R}{L}$ in this circuit is very small, the current is very nearly proportional to flux. If this ratio is not small, negative loops will appear at the tips of the hysteresis loop; but this effect was negligible in the circuit as used, for the ratio could be increased to four times its normal value without causing any suggestion of negative tips.

Fig. 9 shows a normal loop taken at about 94 kilolines, a-c. flux density, and one taken at the same a-c. impressed voltage, but with 8 amperes direct current flowing in the same winding. Both loops are taken to the same scale, and the area of the distorted loop does

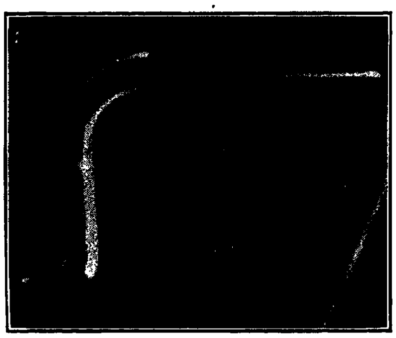

Fig. 9—Normal and Displaced Hysteresis Loops Taken with Bilateral Oscillograph. Their Area Includes Both Hysteresis and Eddy-Current Losses

not differ greatly from that of the normal one. The loop containing d-c. flux shows practically no area in the portion representing high flux density, and therefore practically no loss on this part of the cycle. The addition of direct current causes a shift to the right, of the current vibrator, but there is no effect on the flux vibrator by the steady d-c. flux in the core.

Numerous other loops were taken at various values of a-c. and d-c. flux, and an extensive study was made of the errors in the bilateral oscillograph. It is felt that the loops shown above are free from any but very small errors, and that they very nearly represent the iron loss (both hysteresis and eddy current) by their area.

However, as a further check on the accuracy of these loops, ordinary oscillograms were taken of the exciting current and the voltage induced in an exploring coil on the core. Fig. 10 shows a trace of this negative. The flux wave was plotted by taking the area under the voltage wave, and the hysteresis loop was constructed from this flux wave and the current wave. The constructed loop checks the distorted loop of Fig. 9 very well indeed, if allowance is made for the difference in scales. The applied d-c. voltage and direct-current values were the same in both cases.

Fig. 11 shows two loops taken with the three-coil circuit. The flux vibrator was connected to an exploring coil of five turns wound outside of the main coil on the middle leg. The current vibrator carried a part

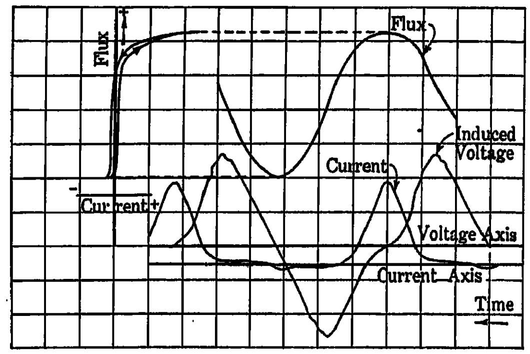

Fig. 10—Displaced Hysteresis Loop Constructed From Actual Current and Voltage Waves. Note that this Loop is Substantially the Same as the One taken with the Bilateral Oscillograph

of the exciting current shunted off at (a) in Fig. 5. The currents were so high that the errors due to leakage and $I\,R$ drop were very pronounced. The area of the loop is actually negative, and is therefore valueless in indicating losses. It does show the change in permeability, though, by the decrease in its slope when the direct current was added. The vertical loop is a normal one, and has very little error, since the exciting current was quite low when no direct current was present. The

Fig. 11—Normal and Displaced Hysteresis Loops of Three-Coil Circuit of Fig. 5, Showing Change in Impedance by a Decrease in Slope when Direct Current is Added. Area of Distorted Loop is not Representative of Iron Loss Because of Errors

distorted loop shows the effect of leakage and $I\,R$ drop at high values of d-c. flux by a decrease in vertical height. The exploring coil did not link as much of the flux when the core was saturated, and the flux was less by the $I\,R$ drop, since the applied voltage was held constant. It should be noted that the average slope of the whole loop from the horizontal axis is a measure of

the a-c. permeability of the iron, or impedance of the reactor.

Impedance Curves

The design which gives the greatest change in impedance for the least number of d-c. ampere-turns is the best, other things being equal. Fig. 12 shows the change in impedance of the reactor as direct current is added. All of these curves are at 60 cycles. In each case the impedance, when there is no direct current, is taken as 100 per cent and the percentage of this impedance plotted for different d-c. ampere-turns. Curve No. 1 is at a low a-c. flux density (42 kilolines) and has the direct current in series (only the center leg of the reactor being used). The initial decrease in impedance

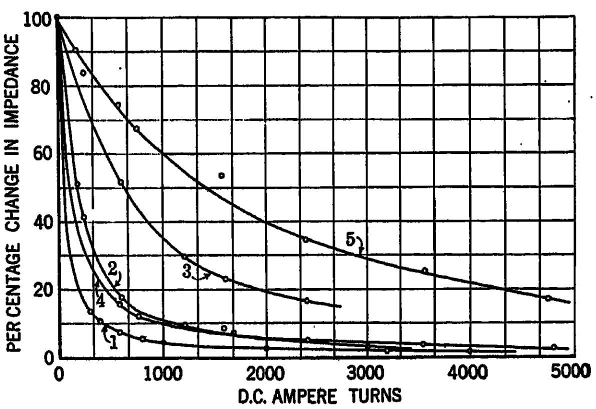

Fig. 12—Percentage Change in Impedance of Reactor with an Increase of D-C. Excitation for Various Connections and Different Values of A-C. Excitation

is seen to be quite large for small values of direct current. No. 2 is the same curve for 70 kilolines, and No. 3 for 94 kilolines. The direct current is most effective at low a-c. flux densities. Curve No. 4 is also at 42 kilolines, but has direct current in the outside legs only. It lies above Curve No. 1 because the middle leg is not affected by the d-c. flux, and the reluctance of the d-c. path is higher than for the series connection. No. 5 is at 90 kilolines and corresponds to No. 3 of the series circuit.

Conclusions

The results of this work indicate that the *iron losses* of a d-c. excited reactor are not excessive. For high a-c. saturations, such as would be used in shunt reactors for voltage regulation on a transmission line, the iron losses proper may even be decreased. However, no scheme has yet been discovered for eliminating the necessary evil of the double frequency circulating current, and its copper loss must really be charged up to the iron. This loss, however, may be made as small as desired by using sufficient copper, since for a given core the double frequency current is a function of the direct current excitation, and by its circulation, tends to cut down the voltage that produces it. Its limiting peak value is the value of direct current if it all flows in the d-c. circuit.

In conclusion, the authors wish to express their appreciation to Dr. V. Bush for his inspiration and assistance during the course of the work and to Messrs. G. Faccioli, A. Boyajian, and O. R. Schurig, for their helpful criticisms and suggestions.

Discussion

J. D. Ball: About ten years ago I was very much interested in investigating the amount and nature of magnetic losses in iron when subjected to a superimposed a-c. and d-c. excitation. We spent three years on this investigation and collected what we could find of the data available at that time. All the results showed quite conclusively that for a given flux change due to alternating current, there was a definite increased loss in the hysteresis if d-c. flux was superimposed upon it, and the greater the superimposed d-c. excitation, the greater the loss. The same conclusion was verified by experiments made at the United States Bureau of Standards, at the Pittsfield Laboratory of the General Electric Company, and also by tests made in the Standardizing Laboratory of the General Electric Company at Schenectady. The results from the various publications studied led us to the same conclusions.

In the present paper the writers state that an attempt was made to account for the additional losses due to a superimposed d-c. excitation by a formula in which the Steinmetz equation was used with changed exponents. This is not accurate. In our mathematical equation the Steinmetz formula was left exactly as it was given by him but it was extended by adding a supplementary expression which would indicate the increased

losses. It is readily seen that to be mathematically correct this additional expression must be added and cannot be multiplied; otherwise the entire expression would become irrational when the d-c. excitation is zero.

There was no certainty expressed at the time that the expression, as supplemented by ourselves, was necessarily correct, but this equation did agree with the results of various experimenters and was satisfied by the data which we obtained.

Our investigation was made for two reasons, first, to assist in the design of machines where those conditions applied, such as in the inductor generator, and in the iron losses in rotor teeth, and second, in the hope that it would stimulate inquiry and result in the subject being studied by other investigators.

The present paper disputes the results obtained up to this time. It is not essential to defend our position taken some time ago; the only thing in which we are interested is in finding the actual facts. The present results are unquestionably correct for the tests made, but I should question whether the authors had the same conditions in their circuits which they thought they had.

I am more than glad additional inquiry has been made on superimposed losses. I do not think it is fair to take the results of this paper as the results of anything except the particular circuits in which they were applied. Since the tests, as the authors are aware, have been made in accordance with what has not been considered good practise for a number of years, I feel they will agree with me on this.

Turning to the paper, the first thing is the question of taking the instrument losses from a primary coil. This was the way it was done for a good many years, and up to fifteen years ago, it was considered the best way possible. The instrument losses and additional current consumed by the instruments are nicely taken care of and it is a simple matter to take out those instrument losses which can be mathematically calculated and you always get something, although not always what is aimed at.

It has been shown by experimenters in magnetic materials that it is necessary to use a potential or secondary coil for a voltage coil to measure the flux, and also to use the potential coil, either the same one or another potential coil, to excite the voltage winding of the wattmeter. I think it was Prof. Epstein who first pointed this out and the fact has been thoroughly established.

Some elaborate tests were made at the Bureau of Standards in Washington and it was pointed out by Dr. Lloyd, and afterwards by Dr. Burroughs, that it was absolutely necessary to use a potential coil to get consistent results in any magnetic testing or investigation which they attempted. That is why I was surprised in glancing over this paper to find a secondary potential coil was not used. I feel that if definite conclusions are drawn, it would be very well to check these results, using the approved method of employing a potential coil.

A second point I wish to make refers to the nature of the magnetic circuit used. Possibly I misread this; but taking Fig. 3, if this represents the same connection as shown in Fig. 1, in which there is a d-c. excitation on the center leg of a three-legged core, and another excitation, a-c. or d-c., on the outer legs, I should take exception to that method of procedure. That isn't exactly superimposing alternating current on direct current. In a three-legged core, flux does quite a number of things and it doesn't all go through the same paths.

Another point: in superimposing alternating current and direct current, I know from experience that you get wild things unless it is done in one definite manner, that is, to have the alternating current and the direct current with one winding right on top of the other, so that any leakage or trouble of any kind would have to be more or less similar.

Another point is that the results obtained from any sample except a ring sample didn't seem to be very good. True, with a ring sample the flux density is greater at the inner circumference than at the outer circumference, but corrections have been established by the Bureau of Standards. We found the only reliable method was to use a large ring in which the mean diameter of the ring was comparatively large in comparison with the width of the sheet, or the difference between the outer and inner radii of the test specimen. Even then certain corrections should be applied as pointed out by the Bureau of Standards and others.

There are at least two definite ways of superimposing alternating current and direct current: One is to subject the test specimen to alternating current and to superimpose on it a direct current in another winding immediately under or over it; another way is the step-by-step method, measuring the losses by the ballistic galvanometer. I think it would be well to check the present tests by the step-by-step method. First, a definite flux change should be assumed which would represent the iron when subjected to the a-c. excitation. The hysteresis loop should then be obtained by the well-known step-by-step method. This is the normal hysteresis loop. To obtain the effect of superimposing d-c. excitation, another loop which I have termed the "unsymmetrical loop" should be taken. This can be done by going up on the saturation curve to some point higher than the maximum of the first loop, then dropping down on the normal hysteresis loop from this second point to a point where the flux change from this new maximum is in the same amount as the total flux change in case of the first loop. Then from this new bottom point, return step-by-step to this new maximum. Rather unique figures are obtained by this method, some of which were published in 1915[1]. We invariably found that with the same flux change the area was always greater when the maximum point from which the loop started was raised. This is the same situation as when you have an a-c. excitation and superimpose upon that excitation a d-c. excitation represented by the mean density between maximum and minimum of the various loops. A study of these figures, the characteristics of any hysteresis loop, and the characteristics of any magnetization curve will show that invariably the area of the unsymmetrical loop increases with increasing mean density, the flux change remaining constant.

A. C. Lanier: The oscillographic record, Fig. 5 in this paper, seems to show a reduction in the density range as well as a change in shape of the dynamic hysteresis loop due to combined a-c.-d-c. excitation as compared with the normal loop. Both effects should increase progressively with the increase in d-c. excitation for large a-c. excitations, and both should cause a diminution in the hysteretic component of the iron loss. The effect upon the eddy-current component is less clear. With small a-c. excitations there should be no appreciable reduction in density range except for very large d-c. excitations. The area of the displaced hysteresis loop for a given density range has also been shown to increase with increasing average density. Therefore, the curves of Fig. 2 appear reasonable.

In connection with the study of surface iron losses, the speaker has noticed that sometimes, with high average gap densities, the measured losses are less than the expected values. The magnetic structure used when these results were observed was a homopolar structure consisting of a slotted cylindrical member rotating within a smooth cylindrical member. The excitation produced radial average flux distribution with a superposed tooth ripple.

At high densities the amplitude of flux pulsation increased less with a given rise in gap density than it did at low densities. The loss increase was correspondingly lower. The seeming discrepancy is traceable to the effect of high tooth saturation which causes a departure from the straight-line relationship between the tooth-ripple density and the average gap density.

Considering these results it seems probable that if the average gap densities had been carried high enough, the flux ripple and

1. The Unsymmetrical Hysteresis Loop, by J. D. Ball, A. I. E. E. TRANSACTIONS, 1915, Vol. 34, page 2693.

the losses due to it might have shown actual decreases with further increase in average gap density.

O. R. Schurig: Mr. Ball called attention to the possibility of errors resulting from the method of iron-loss measurements employed by the authors, if proper corrections are not made.

It is true that the power given by direct primary measurement, that is without the use of a separate potential winding on the iron core, includes losses other than iron losses. If, however, the extra losses are evaluated and corrected correct iron losses are obtained. I believe the paper gives evidence to show that the proper corrections were applied and that reliable results were secured.

It must be pointed out here that the method of iron-loss measurement employing a separate potential-circuit winding on the iron core—the method advocated by Mr. Ball—also involves possibilities of grave errors. The potential-coil method is particularly subject to error where there is leakage flux between the primary (exciting) winding and the potential (exploring) winding to which the wattmeter potential circuit is connected—a well-known fact. Thus, the reliability of any test results on iron losses depends on the thoroughness with which the extra losses have been corrected, unless the circuits have been specially designed to make the excess losses negligible.

It so happens that within the last year the potential-exploring-coil method has been applied at Schenectady to iron-loss measurements with superposed d-c. and a-c. excitations, *i. e.*, a series of tests similar to those presented in the Charlton and Jackson paper, but utilizing, for measurement purposes, a separate potential winding on the iron core under test. The results of these more recent tests, to be published on a future occasion, show, as do those of the paper, a slightly decreasing iron loss with increasing d-c. excitation when high a-c. excitations at constant impressed a-c. voltage were employed.

K. K. Palueff: I should like to mention that if a core as used by the authors is long, a certain portion of the total flux produced by windings placed on the outer legs may not reach the center leg but take an air path for return. The same thing would be true for the flux created by the winding on the inner leg. This "stray" flux will increase as the flux density increases. Thus, the superposition of two fluxes—one created by the winding on the outer legs and another by the winding on the inner leg—may not be as complete as anticipated.

W. R. Weeks (by letter): In the measurement of iron losses under normal conditions, what is known as the Epstein circuit is used to eliminate the $I^2 R$ losses of the exciting winding and wattmeter current coils from the readings. If it is possible perfectly to interlink the excitation coil and the exploring coil, then the readings obtained will be an accurate measure of the losses in the iron. The errors due to circuit-resistance losses will be automatically eliminated.

However, errors may be introduced if there are other circuits which produce flux that links the exploring coil but does not, at the same time, link the exciting coil. Such leakage flux between the two windings will cause errors that will be positive or negative depending on the phase relation of the leakage flux.

There are three possible conditions that may be encountered. (1) If there is no leakage between the exploring and excitation coils, the readings will be correct. (2) If there is leakage between the exploring and excitation coils, and there is no third excitation coil, the readings of the wattmeter will be low. (3) If there is leakage between the exploring and exciting coils and there is a third coil (such as the d-c. winding) which sends flux through the leakage path, the readings of the wattmeter may be high.

All of the above leakage factors are quite difficult to determine for any magnetic circuit such as that used by the authors of the paper, and I believe that using the older method which introduced additional losses, losses that could be accurately determined, was much preferable to trying to use the Epstein circuit.

The Epstein circuit would undoubtedly be better if the exciting coil were the outside strands of a cable of which the central strand was used as the exploring or potential coil.

J. E. Jackson: Mr. Ball has pointed out the fact that the paper was inaccurate as to the exact methods that had been applied in correcting the Steinmetz formula. I am sorry that the mistake was made, but it was intended mainly to indicate that an attempt of some kind *had* been made to adapt existing formulas to the case of superposed excitations.

In answer to the question of why the Epstein method was not used, it was simply because it was felt that with the facilities available, the "subtraction method" was much more reliable. Mr. Weeks has pointed out some of the difficulties encountered in the Epstein method, and, that for the very reason that no one knew what the different fluxes would do when they were superposed, it was impossible to calculate the errors to be expected. If all the leakage factors were accurately known, the calculations would still be more involved than the ones used, and there would be that much more chance of error.

Whether the two circuits used were identical in their behavior or not is still an open question, but the data showed that they were at least substantially alike. Our wattmeter method, when used in the series circuit, was felt to be correct, and the fact that the curves were practically the same when taken with the three-coil circuit tends to prove that the flux paths were very nearly identical in the two cases.

Mr. Ball stated that a study of magnetic characteristics would show that invariably the area of the unsymmetrical loop increases with increasing mean density. I do not believe that this is necessarily true if the analysis is carried far enough. Our hysteresis loops taken with the bilateral oscillograph show clearly that the area is less at the top of a distorted loop, and a consideration of the magnetic theories of Ewing, Poisson, and others shows that this must be the case. Hysteresis is generally regarded as some sort of molecular friction, and when d-c. excitation is added to the core the molecules are lined up and held so tightly that they cannot turn over completely with the reversing a-c. flux, but only vibrate slightly. If the d-c. excitation is strong enough to hold them tightly clamped, the hysteresis loss must disappear completely. The eddy-current loss should not change at all unless the wave form changes, so the net result would be a decrease in iron losses with d-c. saturation. As a matter of fact, the wave forms do become slightly distorted, and the eddy losses tend to go up to some extent.

Our work may not be accurate in the highest degree, but we feel that it is not grossly in error, and that certainly the iron losses do not increase ten or twenty times when d-c. excitation is added, although they may change as much as 100 per cent one way or the other.

Study of Time Lag of the Needle Gap

BY K. B. McEACHRON*
Member, A. I. E. E.

and

E. J. WADE*
Associate, A. I. E. E.

Synopsis.—*The study of high-voltage, steep-wave-front transients is difficult from the experimental standpoint because of the very short times involved. Due to the improvement which the cathode-ray oscillograph has enjoyed in recent years, a device is now available by the use of which transients occurring in times as short as one-millionth of a second or less may be photographed. In the paper, the authors used an oscillograph developed by Dufour in France, with which a brief study was made of the time lag of needle gaps and of a needle to a plane.*

A description of the oscillograph is given including a discussion of the method of operation. The photographic film is placed inside the tube so that the electrons impinge directly on the film. The wave is drawn out along a time axis by the combined action of a sweeping motion and a perpendicular oscillating motion imparted to the electron stream by the action of proper electromagnetic fields.

Tests were made with a wave which was nearly perpendicular, reaching its maximum in about one microsecond. Such a wave was obtained by the discharge of a condenser through a suitable circuit. An oscillogram which shows the wave front used is given, and attention is directed to the 20,800-kilocycle oscillation which appears superimposed on the wave front.

The results of tests in which this wave front was applied to gaps are given and it is shown that with any given gap setting and sparking voltage that the time lags vary through wide limits. It is also shown that, for the same voltage, increased gap settings mean increased lag. The per cent overvoltage required to keep the lag to two microseconds or less decreases as the gap spacing increases.

The Study of Transients

ONE of the most difficult and perhaps also one of the most fascinating problems which the electrical engineer of today is called upon to study is that of the transient phenomena occurring in electrical circuits. Failure of apparatus, caused by the puncture or flash-over of insulation due to overvoltages the duration of which may be of the order of a few microseconds, has made desirable the use of lightning arresters which limit the voltage to safe values. Since in practise many of the steep front traveling waves are the result of the sudden releasing of a bound electrostatic charge, lightning arrester laboratories have used the discharge of a suitable condenser to simulate the actual line condition. For this purpose, and for the study of the action of insulation and gaps, impulse generators have been built which may be charged to values as high as 2,000,000 volts.

The calculation of such transients is not troublesome so long as the voltage is low and the wave front not too steep. However, with the higher voltages and very steep wave fronts, assumptions are often made, the correctness of which is at least open to question. The sphere gaps which are used are assumed to be instantaneous, and the resistance of the gap after arc-over is assumed to be negligible. The inductance and capacitance of the connecting leads is often neglected, while the influence of the test piece itself on the wave shape is frequently unknown. The circuit usually comprises loops which anyone familiar with radio knows are likely to mean coupling that may give rise to erroneous results.

The limitations and some, at least, of the possible sources of error involved in the use of the impulse generator have been recognized by lightning-arrester engineers for some time. Three years ago the authors of this paper began to search for means for recording, on a photographic film, transient phenomena the frequency of which might be a million cycles per second or more. As a result of this search of the literature, the device described in this paper was found.

Oscillographs

The frequency limit of the ordinary Duddell oscillograph is in the neighborhood of 15,000 cycles. At this frequency the errors due to mechanical inertia are large and it is impossible to do more than count the cycles; the wave form cannot be distinguished.

A satisfactory oscillograph for the delineation of the volt or current-time characteristic of a short-time transient must satisfy the following conditions:

1. The device must have no appreciable inertia and must be capable of operating at a frequency of at least one million cycles per second.
2. The device must use little energy in its operation, so that its use will not appreciably disturb the original circuit.
3. The device should be capable of registering both voltage and current simultaneously.
4. The apparatus must be so arranged that a single impulse will be sufficient for a satisfactory photographic impression.
5. The oscillograph should be as simple as possible and have sufficient accuracy so that the results may be used with confidence.

The first point can be satisfied only by some device using the flow of electrons. When thinking of the available devices making use of such a flow, one naturally turns to the Braun tube which has been used for many years as an oscillographic device. As originally developed, the Braun tube consisted of a cathode and an anode in an exhausted tube, together with a fluorescent screen. Unidirectional voltage from a static machine causes a flow of electrons from the cathode to the anode, some of which pass through a small hole in the anode and are deflected by magnetic or electrostatic fields produced by the phenomena being studied. The rays then pass on to the fluorescent screen where a graph is

*Both of the Research Section, Lightning Arrester Engineering Department, General Electric Company, Pittsfield, Mass.

Presented at the Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925, and at the Annual Convention, Saratoga Springs, N. Y., June 22-26, 1925.

traced the coordinates of which are determined by the deflecting fields. If the phenomenon repeats itself the graph appears as a stationary pattern, and may be recorded photographically using an exposure of several seconds.

The Braun tube has negligible inertia, and very little energy is required to cause the deflection of the cathode beam. Its speed is the speed of the electron which may be varied between quite wide limits especially if using a heated cathode as in the Western Electric tube[1]. The upper limit of velocity is perhaps one-half that of light.

The fourth condition mentioned, that of recording a single impulse, may be satisfied by placing the photographic film inside the tube in such a way that the electron stream impinges directly on the film. This has been done by several investigators with marked success. Some additional photographic effect can probably be obtained by the use of the heated cathode, but to get high electron velocities a very good vacuum is required which makes the operating technique more difficult.

Many references have been found in the literature concerning the Braun tube and its uses. Most of this material has been the result of investigations done in foreign countries. All of the early work was done with fluorescent screens which limited the oscillograph to use with phenomena which could be duplicated, since the time of exposure was very long compared to the duration of most transient phenomena.

S. R. Milnor[2] in 1912 reported a volt-ampere characteristic of an arc at a frequency of two million cycles. This work was done with a cold cathode and a fluorescent screen, but he was able to make the phenomenon repeat itself exactly.

The first reference to the use of the photographic film inside the tube appears in an article by Alexander Dufour[3] in *Comptes Rendus* in 1914. He stated that he had obtained on a film a space of 1 millimeter corresponding to an interval of time of one three-millionth of a second. Dufour succeeded in doing this by the use of a method of registration which is described more in detail later in this paper.

In 1919, Sir J. J. Thompson[4] in a lecture before the Royal Institution stated that, when using a hot cathode with the film inside the tube, an exposure of one-hundred thousandth of a second would be sufficient to excite the photographic plate. This reference also mentions the use of an auxiliary deflecting alternating current which produces the time axis and which could also be used for timing the phenomenon.

In a valuable contribution appearing in the *L'Onde Electrique* in 1922 Dufour[5] describes a cathode ray tube which he used successfully with transients up to a fundamental frequency of 750,000 cycles with harmonics showing plainly at a frequency of 3,000,000 cycles. To produce a time axis, Dufour used the rise of current in an inductive circuit to draw out continuous oscillations from an arc generator. He used a cold cathode with the photographic plate inside the tube, the tube being connected to a continuously operating air pump. This apparatus was used in studying the antenna currents in the wireless system on the Eiffel Tower.

In 1921, Dr. D. A. Keys[6], in an article entitled *A Piezoelectric Method of Measuring Explosion Pressure,* used a cathode oscillograph as the indicating device for the determination of instantaneous pressures in explosions under water. In this work Dr. Keys used a heated cathode with the photographic plate inside the tube.

In 1922 Johnson[1] described a tube developed by the Western Electric Company which makes use of the hot cathode. This tube has a much higher sensitivity than the cold cathode tube used by Dufour. With any given tube the sensitivity depends on the speed of the electrons in the cathode stream and on the deflecting force. If high sensitivity is required, the use of the heated cathode will give very good results as it is possible to apply low cathode voltages and secure slow moving electrons. Since the cold cathode depends on positive ion bombardment for the liberation of electrons, quite high voltages are necessary, which means high velocity electrons.

The name of Professor Harris Ryan[7] has been associated with the cathode ray oscillograph for many years, he had a paper on this subject before the institute as early as 1903.

Important work has been done by several investigators among whom may be mentioned Wood[8], Minton[9], and Chaffee[10], but enough has been mentioned to indicate the development of the cathode ray oscillograph in recent years.

THE DUFOUR OSCILLOGRAPH

For the study of high-speed transients then, it appears that no better device is available than the oscillograph developed by Dufour. In the description of this oscillograph which follows, the tube itself is identical with that described by Dufour[5]. The switching apparatus furnished by Dufour has not been used in this investigation*.

Referring to Fig. 1 the oscillograph consists essentially of glass tubes *a* and *b*, fitted by means of a ground joint into the bronze chamber *c*. The upper glass tube *a* carries the cathode and anode. The tube *b* has one pair of deflecting plates for electrostatic deflection of the electron stream. For magnetic deflection two sets of coils, 1–1 and 2–2, Fig. 2, perpendicular to each other, are placed external to the tube and located slightly below the deflecting plates. The coils are arranged so that they may be rotated about the axis of the tube, thus allowing adjustment of the angle between the axes of the deflecting fields.

To operate the oscillograph expeditiously, easy means

1. See list of references at end of paper.

*For a description of this part of the apparatus reference should be had to the work of Dufour.

must be provided for changing films quickly. It is also necessary that a fluorescent screen be arranged so that it can be removed when making an exposure. How this is done in the Dufour oscillograph may be seen by

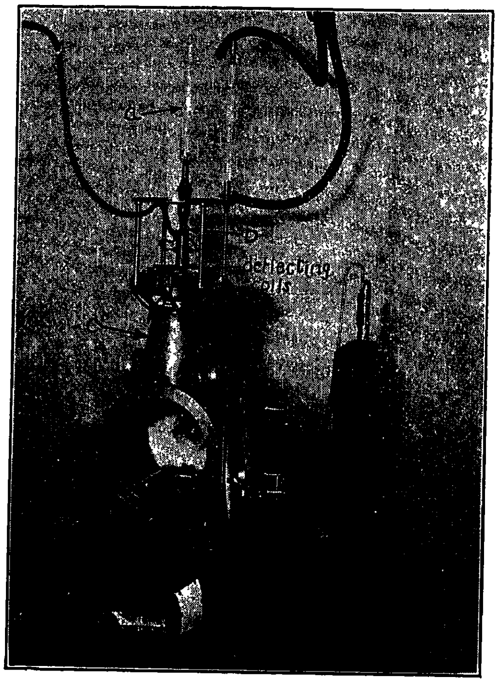

Fig. 1—Dufour Oscillograph

referring again to Fig. 1. The drum, which in the illustration appears in the foreground, is provided with a film magazine which allows six films to be taken in

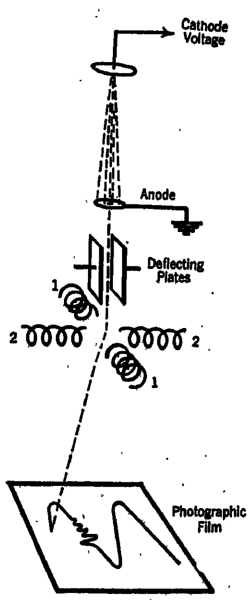

Fig. 2—Diagramatic Representation of Oscillograph Operation

succession. When viewing the phenomenon, a fluorescent screen is turned up into position covering the opening into the interior of the drum so that the films are not exposed when using the screen. After placing the films in the drum, it is placed inside the bronze chamber and locked in position. The opening is closed by a door having a very carefully constructed joint so that the tube may be made air tight. Three cocks, turning in ground joints placed in the door, serve to operate the mechanism for changing films and moving the fluorescent screen. Two glass windows, one on either side of the bronze chamber, permit of easy view of the fluorescent screen.

Operation of the Oscillograph

For slow speed work, a moving drum to take the place of the magazine drum may be used. This drum is driven by means of an external motor and magnetic clutch. A simple calculation shows that such a drum

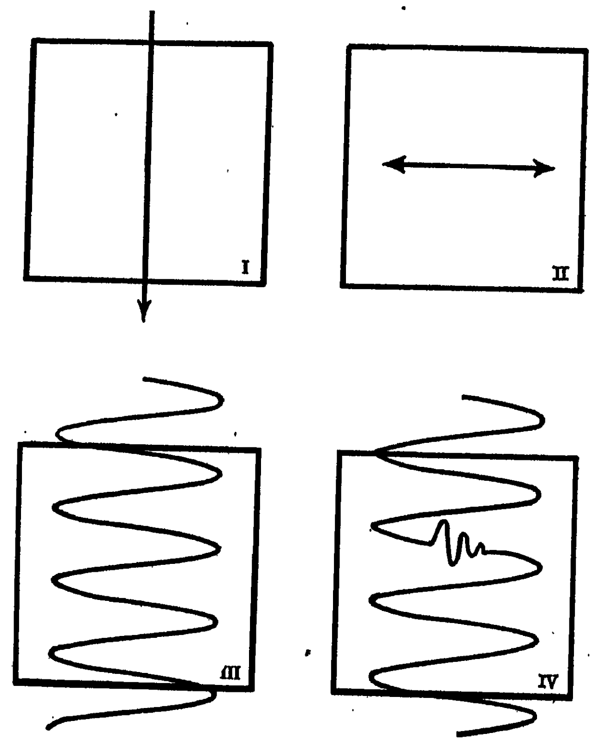

Fig. 3—Method of Registering Transient Phenomena
I. Sweeping III. Sweeping and Oscillator
II. Oscillator IV. Transient superimposed on III

cannot be rotated at a sufficiently high velocity to draw out the oscillations so that they may be studied. To draw out a one-million-cycle wave in a manner similar to that used with the ordinary Duddell oscillograph, so that two millimeters are allowed per cycle, would require a film velocity of 2000 meters (6650 feet) per second.

This problem has been solved by Dufour in a very satisfactory manner. Rather than move the film, the electron stream is subjected to the action of auxiliary fields which draw out the wave without the limitations of a mechanical system, as shown in Fig. 2. The method by which this is accomplished may be understood by reference to Fig. 3. In I is shown the effect of passing a transient current through coils 1-1. With the proper circuit arrangements the beam is held

off the film at the top until ready for the photograph to be taken, when a transient takes place which sweeps the beam across the film holding it off the film at the bottom. This transient current will be referred to as the sweeping current.

A source of high frequency (a vacuum tube oscillator) is connected to coils 2-2, which are mechanically spaced 90 deg. from coils 1-1. With coils 2-2 energized, the oscillator traces a straight line on the film, the amplitude usually being adjusted to utilize the entire width of the film. When coils 1-1 and 2-2 are operated together the oscillator waves are drawn out as seen in III. If the oscillator frequency is 50,000 cycles and the effective width of the film 100 m. m. (3.9 in.), then the average distance corresponding to one microsecond would be 10 m. m. (0.39 in.). This means that if a million-cycle wave were impressed on the deflecting

FIG. 4—IMPULSE GENERATOR

plates so that the beam was deflected thereby in the same direction as by the sweeping current, it would be drawn out sufficiently so that the wave form could be determined and IV shows the effect of the combination of the three fields. The oscillator wave is the zero line for the transient being studied, and it is a time axis whose unit of measure is varying according to the sine law. The speed of sweeping is always a compromise between drawing out the oscillator wave and the difficulty of getting the unknown phenomena timed so as to appear on the film.• With much slower speed phenomena, the sweeping field may be placed 90 deg. from that of the unknown transient, so that the time axis becomes a straight line across the film. This axis may be conveniently calibrated by superimposing a known high frequency using the oscillator coils.

Thus it is possible to get volt-time or ampere-time curves with a time axis which can be calibrated with considerable accuracy. Volt-ampere characteristics may be taken by applying to the cathode stream fields proportional to the voltage and current and spaced 90 deg. apart.

The Cathode Stream

The best registration on the film is obtained when conditions are such that a fine pencil of rays strikes the film only when required. Not only is it desirable to hold the rays off from the film before and after the transient, but the operation of the tube is much improved if the cathode voltage is applied for just sufficient time to allow the proper registration of the unknown transient.

For a given voltage impressed on the cathode the sharpness of the trace on the film will depend on the degree of exhaustion of the tube. For the work described in this paper the authors have used a Langmuir condensation pump, backed up by a two-stage oil pump. A McLeod gage was used to give an indication of the condition of the vacuum but the appearance of the spot on the viewing screen and the character of the discharge from the cathode itself, as viewed with the eye, gives a more accurate determination of the proper operating condition. A small tray of phosphorus pentoxide was kept inside the vacuum chamber which serves to keep the vapor pressure low. The entire tube is always kept in the evacuated condition except when actually changing films. This procedure aids in keeping the gas evolved by the walls of the tube down to a sufficiently low value so that the tube can be worked easily and quickly.

The necessary cathode potential may be obtained by the use of either a high-voltage direct current, or a few degrees of the crest of an alternating potential. The latter method may only be used with phenomena which are fast compared to the change of potential during its registration. This method was mentioned by Dufour as being particularily adapted to the study of very short time transients, and as this method is very convenient it was adopted for use in this study of gap characteristics.

Timing the Transient

The spot made on the photographic film by the electron stream may travel as fast as 80 km. (50 mi.) a second across the film; and since it is not feasible to get a developed registration length of more than 10 or 12 meters (32.8 to 39.2 ft.) on the film, the transient must be initiated during the very short interval of time in which the spot is sweeping across the film.

A rotary switching device has been built which makes the necessary contacts so that voltage is applied to the cathode, the sweeping started, and the unknown phenomenon so timed as to appear on the film. The oscillator is connected before voltage is applied to the cathode, and remains connected until after the exposure has been made. The arrangements are such that only

the pushing of a button is required to set in operation a mechanism which makes all connections automatically.

Time Lag of Needle Gaps

It is known that a needle gap shows considerable lag when subjected to steep wave front impulses. The brief study which is presented herewith measures definitely the lags encountered under the given conditions. The results are not complete, but do give for the first time, as far as the authors are aware, a direct measurement of lags as short as a few microseconds. The methods used here are being applied to the study of the problems encountered in lightning arrester practise and will yield results of great importance.

The time lag of a gap may be taken as the time elapsing until breakdown occurs during which the applied potential exceeds the low frequency spark potential. For a voltage only slightly in excess of the low frequency spark potential the time lag may be long, while with steep wave fronts of high voltage it will be extremely short. The lag with any given gap is determined not only by the voltage at the time of spark-over but also by the shape of the wave front used.

The purpose of these tests is to find the effect of successive increments of overvoltage on the time lag. To avoid the complication of a sloping wave front, it was thought best to use a wave as nearly rectangular as could be obtained. It is impossible to produce a perfect rectangular wave but if the time required for the voltage to reach a constant value is small in comparison with the time taken by the gap under test to spark over, the error will be negligible.

Test Arrangements

An impulse generator, which was built for use in connection with the testing of lightning arresters, was used as a source of voltage. This generator, which may be operated up to 100 kv., consists of two hundred glass plates with tinfoil coatings. The plates are divided into four groups connected in series, each group consisting of 50 plates in parallel, giving a capacity of 0.13 microfarads. The photograph (Fig. 4) shows the compact arrangement of the plates and the kenotron equipment which is used to charge the condenser. A connection diagram is given in Fig. 5 and shows the limiting sphere gap which determines the voltage at which discharge will take place. The water tube resistance, R_1, allows the sphere gap to charge up properly, while R_2 is used to control the wave front as will be shown later. The dividing condensers, C_1 and C_2, were used for reducing the voltage to the proper value for the deflecting plates on the oscillograph. The use of a resistance potentiometer was considered, but if a value low enough to record the wave form accurately was used, it would discharge the condenser too rapidly, so that the voltage applied to the needle gap would not be sustained.

The oil-immersed dividing condensers are shown in Fig. 6, together with the needle gap being tested. These condensers consist of two fixed plates spaced 0.8 mm. (1/32 in.) with a movable third plate having a

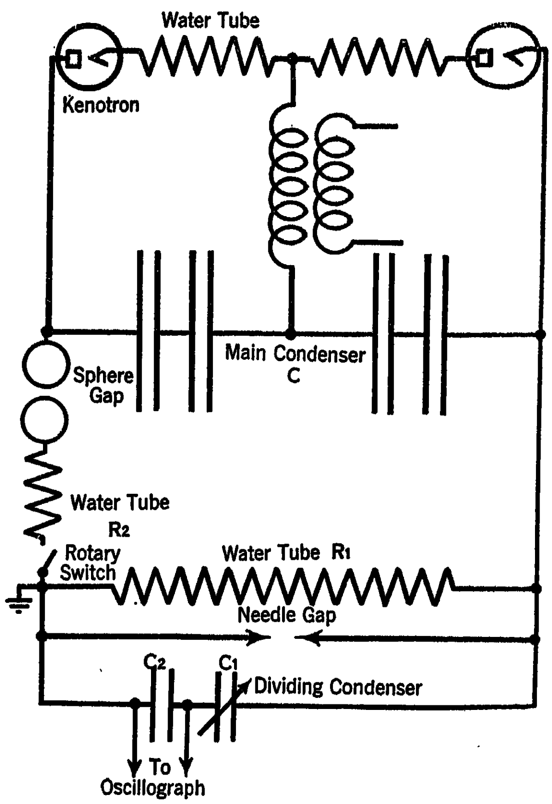

Fig. 5—Connection Diagram

micrometer adjustment. The capacity of C_1 at the setting used on the tests was about 20 micro-micro-farads. Variable stray capacities to ground and inductive effects between the condenser and the oscillograph

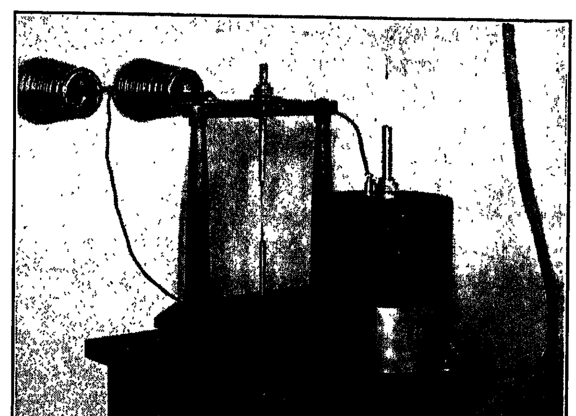

Fig. 6—Dividing Condensers and Test Needle-Gap

were eliminated by using a ground shield around the dividing condenser and by the use of a concentric cable connection to the oscillograph. The grounded sheath of this cable was made of braided bronze wire, the inner conductor being a fine manganin wire having a resist-

ance of about 100 ohms. This resistance was used to damp out oscillations originating in the dividing condensers and lines.

Voltage calibrations were obtained from capacity measurements, and more directly by taking oscillograms when holding a known 60-cycle voltage on the dividing condensers.

The general arrangement of the different elements used in taking a cathode ray oscillogram is shown in Fig. 7. The vacuum tube oscillator may be seen just in front of the oscillograph. The vacuum pumps are not visible, being located under the table directly beneath the oscillograph. The rotary switch is housed in the square box shown at the right. Between the rotary switch and the oscillograph are located the dividing condensers and the test needle gap. The entrance bushings back of the test gap lead to the 200-plate condenser, which is located close to the other side of the wall. When setting up this circuit, care was taken to make all connections as short and direct as possible.

Fig. 7—Laboratory Set-up for the Study of Impulses

Wave Form

Fundamentally, the circuit shown in Fig. 5 represents the discharge of one capacity into another with small series inductance and considerable series resistance. The circuit is of course complicated by the use of series gaps, wires leading to oscillograph and etc. With such a circuit, the series resistance R_2 will increase the time required to charge the capacity of the dividing condenser and connections.

The effect of changing R_2 may be seen by referring to Fig. 8, which shows the wave fronts with three different values of resistance. The method of registration used is the same as that described in connection with Fig. 3 and consists in applying an upward sweeping motion, combined with the horizontal motion of the oscillator. Superimposed is the discharge of the condenser which is initiated by the action of the rotating switch.

On the oscillograms given in Fig. 8 will be found two sets of oscillations, the first being damped out rather quickly. This oscillation, which has a frequency of

Film 593—Oscillator frequency 50 kc. Wave form with 700 ohms series resistance. Voltage reaches constant value in 1.0 microseconds. Needle gap sparks after 0.83 microsecond. Gap setting 65mm. voltage 75 kv.

approximately 20,000 kilocycles, occurs when the rotating switch sparks and is followed by another when the limiting gap sparks. There is a certain variable time interval between the sparking of these two gaps. However, for the purpose of this paper the wave to be studied is that found when the limiting sphere gap sparks. On each of these films time is measured along an oscillator wave beginning at the time when the main condenser discharge begins.

In making these tests the aim was to obtain a steep wave front but at the same time to prevent the voltage from over shooting. Film 300 (Fig. 8) shows the main transient rising to its maximum value in about 2.5 micro-seconds. Superimposed on this wave front are oscillations which are made up of a combination of several frequencies. Film 300, which was taken with 1100 ohms in series, shows that none of the oscillations has a voltage exceeding the maximum value of the main transient.

The series resistance was reduced to 570 ohms and film 304 taken. This film shows that the main transient rises to its maximum in about 0.4 microsecond. This resistance is too small, however, as some of the crest values of the superimposed oscillation exceed the final voltage.

A value of 700 ohms was chosen as being the best compromise between the steepness of wave front and the condition of over-shooting. Film 593 was taken, using this series resistance, and it was found that a time of one microsecond was required for the voltage of the main transient to reach its full value (marked a on the film). This film is interesting as it shows the sparking of a needle gap 0.8 microsecond after full voltage had been applied.

Results of Tests

The time lags under most test conditions used exceeded two microseconds, which made the use of the oscillator undesirable except for timing purposes; therefore, nearly all results were taken with the sweeping only, as this allowed several exposures on one film. With six films and five tests per film, it was possible to get 30 tests before releasing the vacuum and changing the magazine drum. The use of the sweeping also gives a uniform time scale for the measurement of the lag.

The results of nine representative tests are given in Fig. 9. As this type of oscillogram is probably new to most of the readers of this paper, a brief explanation is given. The different tests are numbered in the order in which they were made. In the first test, for instance, which is at the bottom of the film, (No. 543), the cathode spot comes on the film from the left, being swept across the film at a uniform rate corresponding to 4.5 microseconds per mm. About 190 microseconds later the voltage is applied by the operation of the rotating switch. The cathode beam is deflected upward and traces a horizontal line, parallel with the zero axis, until after 140 microseconds the needle gap under test breaks down and the cathode spot falls to zero and so continues, passing off the film at the right. Although the wave front in this film appears perpendicular, it is really as shown in Fig. 8, fi m 593.

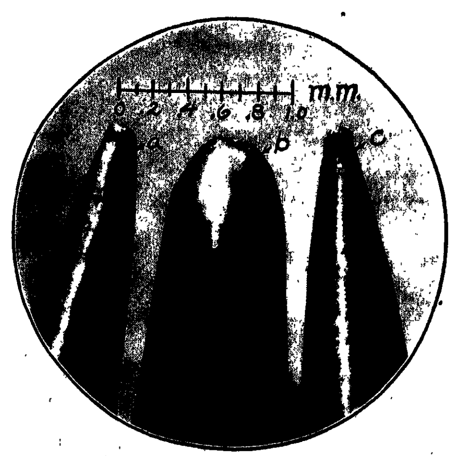

Fig. 10—Condition of Needles after Thirty Discharges
a. New point. b. Dulled point.
c. Extra sharp point.

Four needle-gap breakdowns are given in film 558,

Fig. 9, the voltage being 58 kv. with a needle gap spacing of 60 mm. This film shows a 50-kilocycle timing wave which fixes the time calibration. Fig. 9, Film 543, shows the result of tests on a 15 mm. needle gap with 22 kv. applied. These oscillograms show very nicely the steepness of the wave front compared with the time lags, and also how well the cathode ray oscillograph is adapted to the study of short time phenomena.

Results obtained from a series of oscillograms for three different voltages and with different needle-gap spacings are given in Tables I to III. Tests were also made with a needle to a plane and between needles having different degrees of sharpness. A photomicrograph is given in Fig. 10 showing the different needle points magnified to 30 diameters. This picture shows the condition of the needles after each had been given thirty discharges.

An analysis of the results given in these tables brings out certain relations which are briefly discussed.

For each voltage used the gap setting, corresponding to infinite lag, will be slightly above the 60-cycle setting for that voltage. As the voltage applied to the gap decreased about five per cent in 4000 microseconds due to leakage of the condenser, no attempt was made in these tests to get extremely long lags. The per cent overvoltage above the 60-cycle spark potential necessary to obtain lags of one microsecond or less was found to decrease with increased spacing.

With spacings of 10, 40 and 65 millimeters the per cent overvoltages are 75, 40 and 29 respectively. It is, of course, to be expected that the greater the per cent of over voltage the shorter the time lag. The results show that this is true, in general, although wide variations in time lag occur with every setting and at all voltages.

*Plane was a disk 2¼ in. in diameter.
†See Fig. 10 for degree of sharpness of points.

An examination of the tabulated results discloses the existance of time-lag zones, which indicates that breakdown is more likely to occur within these zones than outside. The existence of these zones is doubtful in some cases, while in others it seems well defined, as for instance at 75 kv. with a 95-mm. spacing (Table III).

In general, the tests show that dull needles give shorter time lags than sharp needles, although more tests should be made to be certain of the relationship.

Comparing the point-plane tests (Point negative, Table IA) with the needle points having the same spacing, the data show that the lags are of the same order of magnitude although the maximum lag with the point-plane is considerably greater than the corresponding value for the points. Tests made with the point positive (Table IB) show that the lag is less than two microseconds while with the point negative with the same spacing and voltage, an average lag of 62 microseconds was obtained. When the point was negative with a spacing of 13 mm. sparking occurred with approximately 50 per cent of the voltage applications. With the point positive a similiar condition was obtained with a spacing of 19 mm. These results give some conception of the effect of polarity on the lag of a point-plane gap.

Measurements of atmospheric conditions were made as a matter of record. Although no correlation with the variation in time-lag could be found, these factors

undoubtedly have a great effect. To determine the effect of these factors much greater variations are necessary than those which occur naturally.

Conclusions

An oscillograph is now available, as represented by that made by Dufour, by the use of which single transients may be photographed, without being limited by the inertia of a mechanical system. By its use, wave forms are shown in the paper having measureable oscillations up to 20,000 kilocycles. The authors have worked with an oscillator frequency of 250 kilocycles which allows the registration of a frequency of 100,000 kilocycles. As the frequency increases, the problem of the characteristics of the circuit used become increasingly important and great difficulty is experienced in keeping the oscillograph circuits free from disturbances emanating from the main impulse circuit. The cathode ray oscillograph, as used here, becomes a tool of the greatest value in the study of transient phenomena.

The lag tests, with constant voltage on the needle gaps, show that the lags vary between wide limits, the average lag increasing with increased gap settings. The limits could probably be narrowed considerably by the use of careful control of air and electrode conditions. The per cent overvoltage, required to keep the lag to two microseconds or less, decreases as the gap spacing increases. The lag is shown to depend on the condition of the needle, the dull needle tending to have the shorter lags.

The authors are continuing the use of the oscillograph, intending to apply it to the study of transients on

transmission lines due to lightning and other causes. The breakdown of insulation and the operation of lightning arresters is also being investigated. Acknowledgment is gladly given to the work of Alexander Dufour, who constructed the oscillograph used by the authors in the work described in the paper.

Discussion

Swampscott, Mass., May 9, 1925

C. H. Dagnall: I should like to ask Mr. McEachron what method he used to have the specified amount of gas—inert gas—inside of a tube to concentrate a stream of electrons into a point. It has been found that when a definite amount of inert gas is present in the cathode-ray tube, due to ionization of this gas, the electrons flowing are concentrated into a very fine stream, instead of spreading out due to repulsion between the electrons and the stream itself. I should like to know what method Mr. McEachron used to produce this definite amount of gas.

H. B. Smith: I think this paper of Mr. McEachron's deserves discussion, and, in my own case, appreciative discussion, because in 1914 we attempted at Worcester to carry out a little of the fundamental research on dielectrics which Professor Adams pointed out the other day as important, as a basis for cable design as well as other things. We wanted to see what could be determined with regard to the analysis of dielectric phenomena occurring when approaching the point of breakdown of the dielectric. We wanted to get polar oscillograms of half waves of current and voltage on a sample of dielectric just previous to the point of breakdown, in order that we might analyze the phenomena going on in the dielectric under that condition.

Now, our first attempt, beginning about 1914, although recognizing the inherent difficulties of any instrument involving inertia, was with the application of the Einthoven galvanometer, which minimizes inertia of parts for the current wave. An electrostatic instrument with a very fine metal filament deflected in an electrostatic field was used to get the voltage wave simultaneously, with a suitable photographic optical system, shutter, etc., so that we might obtain a half wave of both current and e. m. f. on a polar diagram of sixty cycles.

That was not the high speed with which Mr. McEachron has worked, but still it is fairly high, and we obtained very good polar diagrams under those conditions. But the diagrams were of such a character that the more we studied them, the more we were afraid of the inertia effect.

So the next step naturally taken up was the application of the cathode ray, and in that case, we made use of the Western Electric Company's development of the cathode-ray tube, and ran into just the difficulty mentioned by Mr. McEachron with regard to getting a satisfactory photographic impression at that speed. We couldn't do it. We had just about reached that point when we learned of the Dufour instrument and attempted to make use of that. This was around 1917, and the war conditions made it impossible to continue the work.

However, experience with this instrument shows that we can secure such records as are needed for half periods on samples of dielectric, under the unstable conditions approaching breakdown. It offers opportunity for this in a most promising fashion.

W. L. Smith: I was wondering how far it is possible to carry this speed before one runs into the difficulty of the change of inertia of the electron with its speed, limiting the speed of the phenomenon to be measured.

Saratoga Springs, N. Y., June 26, 1925.

E. E. F. Creighton: In the early years of lightning arresters and protective devices development, I spent many hours with Dr. Steinmetz speculating on what might be taking place in the earlier parts of our artificial lightning discharges. We could estimate, in a way, what extremely high frequencies might be brought into existence—superposed on our lightning frequencies which were, as a matter of fact, carried as high as 5,000,000 cycles per second—but there was no assurance that these superposed higher frequencies actually existed to any appreciable degree. The mathematical calculations of the resistance of the "skin effect," for example, indicated that such high frequencies would be damped out immediately. These puzzles of more than twenty years' standing have been carried in our minds. Therefore, to me, personally, it is a most peculiar pleasure to look on these oscillograms of records of millions of cycles per second and see the complete solution of our speculative problem.

I wish to make one correction as to the authors' credit given to Mr. Duddell in the matter of the early work on the oscillographs. There are three men who stand preeminent in the development of the oscillograph—Blondell in France, Duddell in England, and our good friend, Louis Robinson, in America.

André Blondell is, without doubt, the father of the oscillograph. In 1898 I passed through London on my way to Paris and spent a day with Mr. Duddell. He was just getting his oscillographic work under way at that time. Upon arrival in Paris I found that M. Blondell had had his oscillographs in use for a long time. He had both the magnetic-needle type and the bifilar type which is in such universal use today. The practical oscillographic apparatus which all of us know and find so convenient to use is entirely the work, one might say, of Mr. Robinson.

L. R. Golladay: I was interested in the author's investigation of the impulse circuit resistance to give most nearly a vertical wave front. It seems to me that a moderate amount of overshoot with a steeper wave front might not be objectionable. If the frequency of oscillation were high enough, the effects on the time lag of the alternate half-waves would, at least approximately, cancel out.

The authors conclude that the percentage of over-voltage required to keep the lag at two microseconds or less, decreases as the gap spacing increases. This conclusion must be based on data not included in the paper. It is to be inferred from Pedersen's work that the percentage of over-voltage to keep the time lag constant with increasing gap length would increase.

I have referred above to the work of P. O. Pedersen who has published two important papers on spark lag in the *Annalen der Physik*. His method makes use of the velocity of spreading of Litchtenberg's figures, and of the velocity of propagation in conductors, to measure time lags of the order of 10^{-8} seconds. The present paper indicates that very careful work is required to obtain consistent results in measuring times as short as those measured by Pedersen. A few of the latter's conclusions are as follows:

(a) For constant gap length, the time lag decreases as the excess voltage increases. A similar conclusion is reached in the present paper.

(b) For constant surge voltage, the time lag decreases to zero as the gap length is shortened.

(c) Effects of electrode shape.

1. For equal gap lengths, needles and points are faster than sphere-gaps.

2. For equal time lags, a needle gap is about one-third longer than a sphere-gap.

3. With a gap of 3 mm., and about 100 per cent excess voltage, the time lag of a 10-mm., diameter sphere-gap was found to be 10.5×10^{-8} sec., and of a needle gap, 5.6×10^{-8} sec., at the same voltage.

4. The time lag of a gap is determined almost entirely by the shape of the anode, and the cathode has practically no effect. This accounts for the results obtained with a gap between a point and a plane in the present paper.

(d) A minimum time lag is obtained with clean electrodes, which may be multiplied by five or more by contamination of the electrodes surface. The effect of a spark is to increase the time lag for subsequent sparks due to corrosion of the electrode surface.

(e) Time lag depends more upon the ratio of impressed voltage to breakdown voltage, than upon gap length, although there is a slow increase with increasing gap length.

The above results were obtained with relatively short gap lengths—usually of a few millimeters. It is interesting to note that Pedersen found that the time lag is more affected by the electrode surface than by the electrode shape.

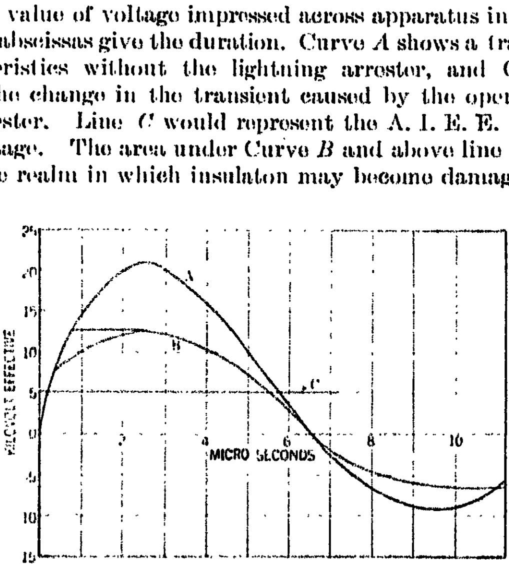
In the course of lightning-arrester development work, the writer had occasion to develop a means for measuring time lag of insulator flashover, breakdown of spark-gap, and discharge of lightning arresters. Satisfactory answers to these problems were obtained with a "timing" circuit consisting of a condenser and resistance connected in series and shunted across the apparatus to be timed. The peak voltage of the condenser is measured by a small sphere-gap in the case of long time lags, or by a klydonograph in the case of short time lags. With the assumption that the voltage impressed on the timing circuit has a rectangular wave shape, the time is given by the formula $t = R\,C \log_e \dfrac{E}{E - e}$, where R and C are the constants of the timing circuit, E the surge voltage, and e the condenser voltage. With this method we have obtained a figure of 2.7 microseconds for the time lag of a 25-kv., pin-type insulator with 150 kv. impressed. The time lag of a 25-cm., sphere-gap set at 8.5 mm., was 0.24 microseconds with 36 kv. While the sphere-gap is fast, it is not instantaneous. It has a measurable time lag.

As a matter of interest some tests were made under one of the conditions of the present paper, a 12-mm. needle gap at 22 kv. A 0.1-microfarad condenser supplied the surge through a 675-ohm resistor. The results obtained were: minimum time lag, 0.83; average 3.3; and maximum 13.8 microseconds. These results are of the same order but somewhat lower than those of the paper. I believe that the discrepancy is due to differences in tests conditions. The results with the needle gap were quite erratic compared to those obtained with sphere-gaps. The major inconsistencies are probably due to microscopic differences in the needles. The smaller differences are encountered when testing with sphere-gaps and are probably due to minor changes in test conditions.

E. E. Burger: One of the most important uses of the cathode-ray oscillograph at the present time is to study the operation of lightning arresters. Heretofore, we have had to rely chiefly upon sphere-gaps for measurements but since only maximum values could be measured and the time element was not considered, questions of uncertainty always accompanied the measurements. By applying this oscillograph to lightning-arrester test circuits a new field of information has been opened for study.

In the study of lightning arresters, there are two important points that we wish to consider from the protection standpoint. First, how much above the insulation test voltage do the arresters allow the voltage of the transient to go, and second, what is the duration of this over voltage? Most insulation has a test voltage of approximately two times normal for one minute. Studies of the mechanism of insulation breakdown seem to indicate that insulation failure depends upon an overvoltage-time characteristic.

The accompanying curves show two cathode-ray oscillograms transcribed into rectangular coordinates. The ordinates represent the value of voltage impressed across apparatus insulation, and the abscissas give the duration. Curve A shows a transient's characteristics without the lightning arrester, and Curve B shows the change in the transient caused by the operation of the arrester. Line C would represent the A. I. E. E. value of test voltage. The area under Curve B and above line C represents the realm in which insulaton may become damaged.



Oscillograms Showing Rise of Voltage (A) Without and (B) With Lightning Arrester.

Now the question is: what kinds and shapes of transients shall we apply to arresters? In the laboratory it is possible to produce transients of almost any wave front, voltage or duration, but we do not know how these transients compare with what we actually get in practise. This is one of the most important points we should know, and possibly through the use of this oscillograph or other instruments, we may be able to determine some of these factors.

L. T. Robinson: In connection with this instrument, it is interesting to recall that as early as 1903 a device making use of the cathode-ray tube for obtaining photographic records of electrical wave forms was developed and described by our past-president, Harris J. Ryan.[2]

K. B. McEachron: No direct determination of the correct amount of residual gas is made. The condition of the vacuum for proper focusing is determined by observing the appearance of the cathode stream. To be able to judge properly the size of the spot in this manner requires some experience on the part of the operator. The gage shows a pressure of from 2 to 6 microns, but the gage indication is not depended upon for determining the proper vacuum condition.

The question of limitation of the oscillograph raised by Professor W. L. Smith is an interesting question. The electron speed corresponding to the voltage used is about one-third that of light. At this speed the limitation does not depend on the velocity of the electrons but rather on means of drawing out the wave along a time axis.

We have used oscillator frequencies as high as 1,000,000 cycles, detecting frequencies on the unknown transient of more than 100,000,000 cycles. Still higher frequencies may be studied but the sweeping rate becomes so high that it is difficult to time the phenomena properly. For most work it is doubtful if much is to be gained by going to frequencies higher than this.

Concerning the effect of spacing on the percentage of overvoltage required to keep the lag to less than two microseconds, mentioned by Mr. Golladay, the detailed data were not included in the paper, but the data for three different spacings were given

1. The Cathode-Ray, Alternating-Wave Indicator, by Harris J. Ryan, A. I. E. E. Transactions, Vol. XXII, 1903, page 539.

in the text near the end of the paper. The results in the table are for lags of two microseconds or longer.

The results obtained by Pedersen are of interest, but as Mr. Golladay states, they were obtained on relatively short-gap lengths with which electrode conditions are of greater importance than with larger gaps.

The time lags on the insulation and sphere-gap as given by Mr. Golladay are of note, but the results will depend considerably on the wave shape applied. Considerable error may be introduced when using this method by assuming a perpendicular wave form for calculation purposes.

Mr. Golladay used a much smaller sphere-gap setting than is standard for 25 cm. spheres which is probably the reason for the rather long time lag given. Peek[3] has shown that considerable lag may be expected with gaps much smaller than $0.3\sqrt{R}$, where R is the radius of the sphere in centimeters.

Oscillographic Solution of Electromechanical Systems

BY C. A. NICKLE[1]

Associate, A. I. E. E.

Synopsis.—*A simple and practical method has been developed for investigating certain important classes of dynamic systems, as represented, for instance, by a power system comprising synchronous or induction generating units, with prime movers, connected through transmission lines to receiving apparatus of the same character. The behavior of individual units, of course, can also be investigated,—such as the important case of determining the current pulsation of a synchronous motor driving a reciprocating compressor, or purely mechanical systems involving moving masses and resilient members, such as beams, bus bars, etc., under the influence of suddenly applied load. In the present paper, the method is described and its application to a few of the possible cases is illustrated.*

The method is to have an "equivalent electrical circuit" solve the problem, and the oscillograph plot the solution. The idea is based on the fact that if the differential equation for an electric circuit is identical with that for the dynamic mechanical system in question, then the corresponding electrical quantities can be taken to represent quantitatively the actual mechanical quantities. The equivalent circuit can be easily set up, and oscillographic records of the voltages and currents constitute the plotted solutions.

The chief value of the scheme lies not only in one's being able to easily solve a given complicated problem, but also in the facility with which the effect of change in design factors may be determined.

*The method is capable of considerable extension. Its application is limited only by the extent to which circuit elements of the proper characteristics can be found. The treatment given here considers only those cases which involve the circuit elements L, C, and R, and in which these are constant.**

MATHEMATICAL analysis of mechanical and electro-mechanical dynamic systems, such as, for instance, a modern power system as a whole, or individual power units, becomes complicated very rapidly as the number of degrees of freedom is extended. When the limit of practical mathematical solution is reached, it is possible to resort to graphical methods which may be effectively employed within a limited field. Such methods were carried to unusual limits in a recent investigation by Booth and Bush[2] which demonstrated the efficacy, and also indicated the limitations, of those methods. Many practical power systems, nevertheless, extend far beyond such limits, yet the importance of their solution is certainly no less. On the contrary, it is perhaps greater.

A simple method has been developed for investigating systems of this general character. It involves the use of the oscillograph in connection with electrical circuits in which the electrical quantities represent the mechanical quantities of the actual system. In any given problem the procedure is to sketch out the equivalent circuit according to definite principles, merely by an inspection of the diagram of the actual system. The equivalent circuit, described later, usually comprises batteries, inductances, capacities, and resistances of appropriate values. Oscillographic records of the currents and voltages in the various circuit branches, following some disturbance, constitute the *plotted solutions* of the differential equations of the system—plotted against time to a definitely known scale of torque, speed, displacement, power, etc. The method thus brings within practical reach the solution of extremely complicated problems relating not only to power systems but also to *any* system for which an equivalent circuit can be set up.

HISTORICAL

The idea of analogous systems has been employed for many years as an aid in visualization, explanation, and mathematical analysis. The same differential equation may represent many different natural phenomena; which means, of course, in each case, that the quantities expressed vary with respect to each other in precisely the same manner. Thus, analogies follow, and electrical engineers have been quick to utilize them in the analysis of many problems. Arnold[3] has extended such analogies to the use of equivalent electrical circuits in the mathematical analysis of problems. While this usually affords a clearer conception of the problem, and may sometimes facilitate the handling of mathematical expressions, nevertheless, the expressions still remain to be handled.

In the present paper, the idea is carried a step further. The mathematical processes are eliminated altogether by having the electrical circuit solve the problem, and

the oscillograph plot it. So, instead of tedious equations perhaps hopeless of solution even with such aid in mathematical treatment as the analogous circuits may give, one has available in the present oscillographic method, practical and simple facilities for analysis.

PREMISES

The fundamental basis for the method is that the differential equations for the equivalent circuit are of exactly the same form as those for the actual system. Since the equations are of the same form, the electrical quantities which occur in the equations for the equivalent circuit may be considered to represent the physical quantities which occur in the equations for the actual system. As will be shown later, if we choose inductance to represent mass, and electrical charge to represent displacement or length, time being common to both systems, it will be found that the differential equations are of exactly the same form, and, furthermore, that the various phenomena occurring in the physical system are represented by quantities in the equivalent circuit which are convenient to measure, that is, voltage and current.

Assuming for the present that these representations are the most advantageous, Table I can at once be constructed.

TABLE I

Mechanical System				Electrical System	
mass	M			$\mathfrak{L}$	inductance
length	L			Q	charge
time	T			t	time
Derived quantities		Dimensions	Dimensions		
force	F	$M L T^{-2}$	$\mathfrak{L} Q t^{-2}$	E	voltage
velocity	V	$L T^{-1}$	$Q t^{-1}$	I	current
damping constant	K_d	$\frac{F}{V}$	$\frac{E}{I}$	R	resistance
resilience constant	K_r	$\frac{L}{F}$	$\frac{Q}{E}$	C	capacity

In general, however, it is not desirable to use Table I for quantitative representation, since this would often require very large and impracticable electrical units. In order that the electrical units shall be of reasonable magnitude, we can let one unit of mass be represented by a units of inductance, one unit of time in the physical system by b units of time in the electrical system, and one unit of length by c units of charge. Then, by arbitrary choice of the conversion factors a, b, and c, the order of magnitude of the quantities in the electrical circuit can be made any desired value. Introducing the conversion factors, Table II may be constructed.

In the differential equations for systems in rotation, the moment of inertia corresponds to mass in systems in translation, angle corresponds to length, and time is the same for both systems. Hence the table for systems in rotation may be written at once, as shown in Table III.

TABLE II

Mechanical System		Conversion Factors[4]	Electrical System	
mass	M	a	$\mathfrak{L}$	inductance
length	L	c	Q	charge
time	T	b	t	time
Derived quantities				
force	F	$\frac{a\,c}{b^2}$	E	voltage
velocity	V	c/b	I	current
damping constant	K_d	a/b	R	resistance
resilience constant	K_r	b^2/a	C	capacity
power	$F\,V$	$\frac{a\,c^2}{b^3}$	$E\,i$	power

TABLE III

Rotational System		Conversion Factor	Electrical System	
moment of inertia	I	a	$\mathfrak{L}$	inductance
angle	θ	c	Q	charge
time	T	b	t	time
Derived quantities				
torque	$\mathfrak{J}$	$\frac{a\,c}{b^2}$	E	voltage
angular velocity	ω	c/b	i	current
damping constant	$\mathfrak{J}_d$	a/b	R	resistance
resilience constant	$\mathfrak{J}_r$	b^2/a	C	capacity
power	$\mathfrak{J}\,\omega$	$\frac{a\,c^2}{b^3}$	$E\,i$	power

In the present treatment, only physical systems, in translation or rotation, in which existing forces are proportional to $\frac{d^2 x}{d t^2}$, $\frac{d x}{d t}$, and x, will be considered, where x represents length or angle; in other words, only physical systems which may be expressed by linear differential equations will be taken up.

A composite system, of which the component parts are expressible by linear differential equation, is itself expressible by a linear equation of higher order and may be represented by a composite electrical circuit.

Obviously the method is not limited to problems in mechanics alone, but may be used as a means of solution of any problem which may be expressed by linear differential equations. However, the method is not necessarily limited to linear systems only. If electrical circuits can be devised which have characteristics varying in exactly the same manner as the characteristics of the system to be solved, then the method is

4. (Mechanical quantity) × (conversion factor) = (electrical quantity). Thus, $C\,L$ feet = Q Coulombs, $V\,c/b$ feet per sec. = amperes, etc.

applicable. In general, this would require resistances, capacities, and voltages which should be variable in accordance with certain prescribed laws. This might, in many cases, be entirely feasible, as is demonstrated in the representation of governor action described in Appendix A.

Equivalent Circuits

Fig. 1 illustrates some elementary physical systems and their equivalent electrical circuit.

A brief inspection of the familiar differential equations for the various cases shows that they are of exactly the same form and, hence, their solutions must be of the same form.

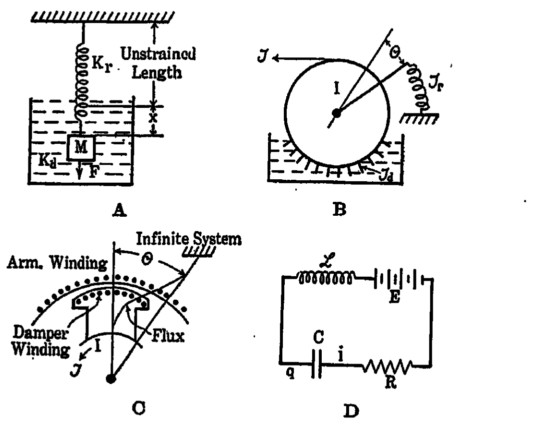

FIG. 1—SYSTEMS REPRESENTED BY THE SAME DIFFERENTIAL EQUATION

(A)

$$M\frac{d^2x}{dt^2} + K_d\frac{dx}{dt} + \frac{1}{K_r}x = F$$

$$M\frac{dV}{dt} + K_d V + \frac{1}{K_r}\int V\,dt = F$$

(B)

$$I\frac{d^2\theta}{dt^2} + \mathfrak{J}_d\frac{d\theta}{dt} + \frac{1}{\mathfrak{J}_r}\theta = \mathfrak{J}$$

$$I\frac{d\omega}{dt} + \mathfrak{J}_d\omega + \frac{1}{\mathfrak{J}_r}\int\omega\,dt = \mathfrak{J}$$

(C)

$$I\frac{d^2\theta}{dt^2} + \mathfrak{J}_d\frac{d\theta}{dt} + \frac{1}{\mathfrak{J}_r}\theta = \mathfrak{J}$$

$$I\frac{d\omega}{dt} + \mathfrak{J}_d\omega + \frac{1}{\mathfrak{J}_r}\int\omega\,dt = \mathfrak{J}$$

(D)

$$L\frac{d^2q}{dt^2} + R\frac{dq}{dt} + \frac{1}{C}q = E$$

$$L\frac{di}{dt} + Ri + \frac{1}{C}\int i\,t\,d = E$$

Case A represents a mass and spring with one end of the spring attached to an immovable support, and having the mass constrained to move in a bath which is assumed to give a damping force proportional to the velocity of the mass M. Comparison of the equations for Case A and Case D shows at once that mass in the physical system is represented by the inductance in the electrical circuit, and length, by charge, time being the same for both systems. From Table I, force should be represented by voltage, the damping constant by resistance, the resilience constant by capacity, and velocity by current. These relations all exist respectively in the two sets of equations, and therefore, Case D is a true representation of Case A. A sudden application of force on the mass M is given by a sudden application of voltage. The voltage across the inductance then gives the inertial force of the mass; the voltage across the condenser C is a measure of its charge, and thus gives both the displacement of the spring and the displacement force; the voltage across the resistance R gives the damping force of the liquid on the mass; and the current in the circuit gives both the velocity of the mass and the rate of change of displacement between the two ends of the spring, these velocities being the same since the support is immovable.

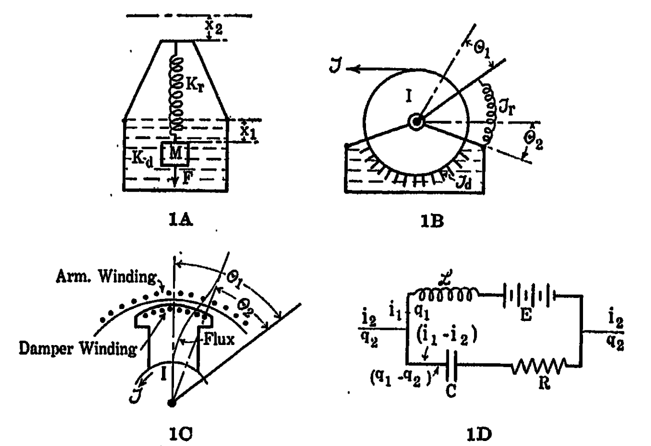

FIG. 2—SYSTEMS REPRESENTED BY THE SAME DIFFERENTIAL EQUATION

(A)

$$M\frac{d^2x_1}{dt^2} + K_d\left(\frac{dx_1}{dt} - \frac{dx_2}{dt}\right) + \frac{1}{K_r}\left(x_1 - x_2\right) = F$$

$$M\frac{dV_1}{dt} + K_d\left(V_1 - V_2\right) + \frac{1}{K_r}\int\left(x_1 - x_2\right)dt = F.$$

(B)

$$I\frac{d\theta_1}{dt^2} + \mathfrak{J}_d\left(\frac{d\theta_1}{dt} - \frac{d\theta_2}{dt}\right) + \frac{1}{\mathfrak{J}_r}\left(\theta_1 - \theta_2\right) = \mathfrak{J}$$

$$I\frac{d\omega_1}{dt} + \mathfrak{J}_d\left(\omega_1 - \omega_2\right) + \frac{1}{\mathfrak{J}_r}\int\left(\omega_1 - \omega_2\right)dt = \mathfrak{J}$$

(C)

$$I\frac{d^2\theta_1}{dt_2} + \mathfrak{J}_d\left(\frac{d\theta_1}{dt} - \frac{d\theta_2}{dt}\right) + \frac{1}{\mathfrak{J}_r}\left(\theta_1 - \theta_2\right) = \mathfrak{J}$$

$$I\frac{d\omega_1}{dt} + \mathfrak{J}_d\left(\omega_1 - \omega_2\right) + \frac{1}{\mathfrak{J}_r}\int\left(\omega_1 - \omega_2\right)dt = \mathfrak{J}$$

(D)

$$L\frac{d^2q_1}{dt^2} + R\left(\frac{dq_1}{dt} - \frac{dq_2}{dt}\right) + \frac{1}{C}\left(q_1 - q_2\right) = E$$

$$L\frac{di_1}{dt} + R\left(i_1 - i_2\right) + \frac{1}{C}\int\left(i_1 - i_2\right)dt = E$$

Similar reasoning applies to Case B, except that the electrical quantities are interpreted in terms of rotation instead of translation.

Case C represents a synchronous machine connected to an infinite system. In this case the voltage across the condenser gives the synchronous torque of the machine due to the displacement of the rotor from the

terminal voltage; the charge on the condenser gives the angular displacement of the rotor from the phase of the terminal voltage; the voltage across the resistance gives the damping torque due to the amortisseur winding, and the current gives the velocity of the rotor with respect to the terminal voltage, that is, the departure of the rotor from synchronous speed. It should be noted that the assumption of direct proportionality between synchronous torque and displacement angle has been made. Although this is not rigorously true, nevertheless for small angles the assumption is, of course, justifiable.

If the capacity in the circuit is made infinite, the synchronous torque becomes zero, leaving only the damping torque. *The circuit is then evidently the representation of an induction motor.*

In the more general case, the supports are not immovable, but also have a velocity and displacement which are functions of time. Fig. 2 illustrates this condition.

Inspection of the respective differential equations shows that they are of exactly the same form as those for the equivalent circuit. Hence, for Case A and Case D the voltage across the inductance gives the inertial force of the mass; the current in the inductance gives the absolute velocity of the mass; the voltage across the condenser, the displacement force of the spring; the charge on the condenser, the displacement

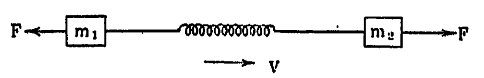

Fig. 3

between the two ends of the spring; the voltage across the resistance, the damping force acting on the mass; the current in the condenser, the rate of change of displacement of the two ends of the spring; and the current in the circuit terminals, the speed of the end of the spring.

The reasoning for Case B is the same except that the electrical quantities are interpreted in terms of rotation instead of translation.

For Case C, the velocity of the rotor is represented by the current in the inductance; the velocity of the terminal voltage is represented by the current in the circuit terminals; the displacement of the rotor from the bus is given by the charge on the condenser; the synchronous torque, by the voltage on the condenser; the damping torque, by the voltage across the resistance; and the relative velocity of the rotor with respect to the terminal voltage, by the current in the condenser.

The characteristics of a transmission line are such that the power transmitted over the line, and the torque corresponding to it, are proportional approximately to the sine of the angle of displacement between the terminal voltages. Rigorous representation of such a characteristic would require a condenser the capacity of which is a sine function of the charge. It has been found, however, that for displacements of the magnitude customarily encountered in practise, the torque may be taken as proportional to the angular displacement[5].

For such an assumption, the transmission line will evidently be represented in the equivalent circuit by a condenser, just as in the case of the spring.

In certain cases, such as power systems, the variation in speed of the component parts may be of relatively small magnitude compared with the total speeds. Since motion is purely relative, any constant value of speed may be taken as a reference. The actual choice of this reference will be largely determined by the nature of the problem under consideration. If every part of the system is initially moving at the same speed, the logical reference point is this initial speed. For such a case, the relative initial speed of each component part with respect to this reference is, of course, zero, and since current in the equivalent circuit represents speed in the actual system, the initial currents in every part of the equivalent circuit must be zero.

Now, for constant speed in the actual system, Σ torques acting on the rotor of each unit must be zero. These conditions impose on the equivalent circuit that

(a) all initial currents must be constant and equal to zero, and

(b) Σ voltages acting on the individual inductances must be zero.

As an illustration, let Fig. 3 represent a mechanical system in equilibrium, the entire system traveling at an absolute velocity V. To an observer also moving at the velocity V, the system will, of course, appear stationary; that is, with respect to the velocity V as a reference, the relative velocity of the entire system is zero. Now, if one of the forces is suddenly changed to a new value, the observer at velocity V will note certain velocities in the various parts of the system as functions of time, while to a stationary observer every velocity will be different by V. Evidently, therefore, the speed of the observer will have no effect upon the other phenomena such as forces, relative displacements in the system, etc.

For systems initially in motion, it is thus possible to obtain an equivalent circuit in which the currents all differ from the actual equivalent currents by a constant, without changing the performance of the circuit.

Use of this principle is made in developing a representation of certain prime mover torque-speed characteristics.

Fig. 4 shows a typical torque-speed characteristic for a waterwheel with full load gate opening held constant. If the waterwheel is initially operating at point C, then for considerable variations in speed, the characteristic is essentially the straight line A tangent to the

5. The relation between power and angular displacements between the voltages at the ends of a transmission line is shown in the paper by Bush and Booth, on Power System Transients, Journal, A. I. E. E., March, 1925, Vol. XLIV, No. 3, page 233.

actual characteristic at C. The equation of line A is

$$\mathfrak{T} = \mathfrak{T}_0 - Ks \qquad (1)$$

where

$\mathfrak{T}$ = torque at any speed s

$\mathfrak{T}_0$ = intercept of line A with the Y axis

and

K = the numerical value of the slope of the line A.

In accordance with the foregoing, since it is desirable in the interest of accuracy to choose some speed other

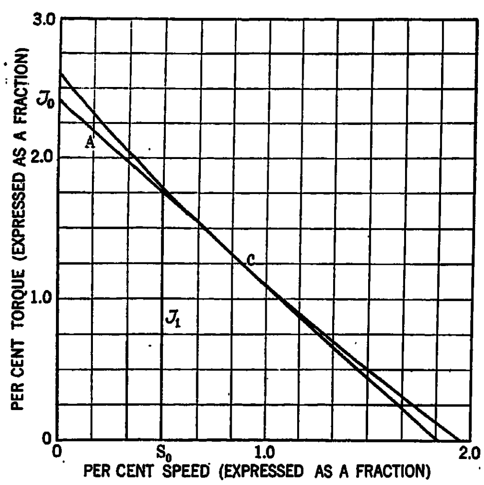

FIG. 4—SPEED-TORQUE CHARACTERISTIC

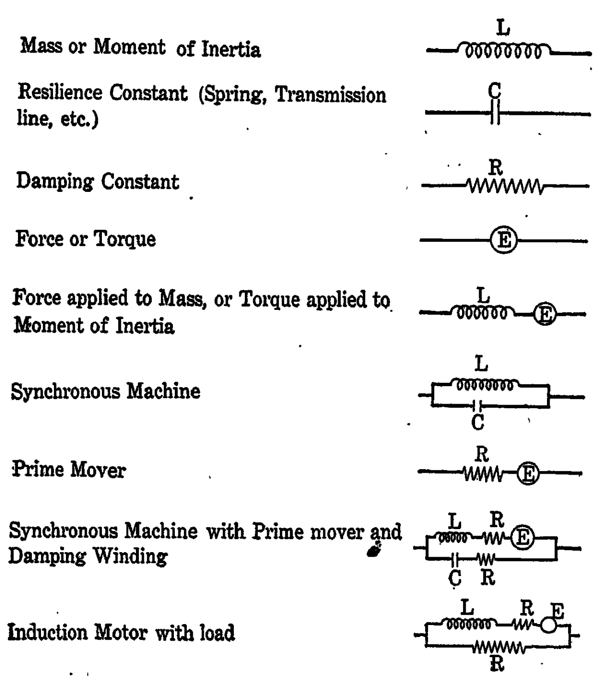

FIG. 5—EQUIVALENT CIRCUITS

than zero as the reference speed, let s_0 be the reference speed with respect to which other speeds are to be measured. Then, since the slope of the line is of course not changed by the choice of reference, the general equation is

$$\mathfrak{T}' = \mathfrak{T}_1 - K(s - s_0) \qquad (2)$$

where $\mathfrak{T}'$ = the torque at any relative speed $(s - s_0)$

and $\mathfrak{T}_1$ = the torque when the relative speed is zero.

That is,

$\mathfrak{T}_1$ = the ordinate of the line A at the reference speed s_0.

In the equivalent circuit, torque is represented by voltage and speed by current. Hence, corresponding to Eq. 2, the prime mover torque at any relative speed will be represented in the equivalent circuit by

$$e = E - Ri \qquad (3)$$

The quantity K, or the slope of the torque speed characteristic, is thus represented in the equivalent circuit by a resistance.

For other gate openings, the slope of the line A and its intercept with the Y axis will have other values. Under actual conditions, the governor will change the gate opening as a certain function of time thus necessitating values of E and R in equation (3) which are also functions of time. An approximate method of obtaining the proper functions for these quantities is illustrated in the representation of the governor given in Appendix A. However, under transient conditions it requires from two to four seconds for the governor to function; hence, the phenomena may be investigated, at least approximately, during the first second or two under the assumption of constant gate opening.

In all equivalent circuits, the inductances, which are used to represent inertia, possess a certain amount of inherent resistance. This resistance, however, can always be considered as a part of the resistance required to represent the torque-speed characteristic. Oscillograms of voltage across the terminals of the various inductances to obtain inertial forces will include the small resistance drop due to the inherent resistance of the reactor. To obtain the true inductive voltage it is, of course, only necessary to subtract the resistance voltage at each instant from the total voltage.

The equivalent circuits for the individual elements of the system, such as generators, motors, transmission line, etc., have been established, and are shown in Fig. 5. It is now necessary to show how these must be connected in a combined, equivalent circuit to represent the system as a whole.

Referring to Fig. 6, let any number of synchronous and induction machines A, B, C, etc., including generators, motors and synchronous condensers, be connected to the bus m m. The conditions which must be satisfied are:

(1) Σ power flowing *to* point o must equal zero.

(2) The speed ω of all branches must be the same at the point o, being the synchronous speed of the bus.

(3) Therefore, Σ torques, corresponding to the various values of power, and to that speed, must be zero.

Thus, by (1),

$$\Sigma\, p = o = p_a + p_b + p_c + p_d + \ldots .$$

By (2)

$$\omega_a = \omega_b = \omega_c = \omega_d \ldots\ldots\ldots = \omega_0$$

By (3)

$$\Sigma\, T = O$$

Fig. 6B shows the equivalent circuits for the various

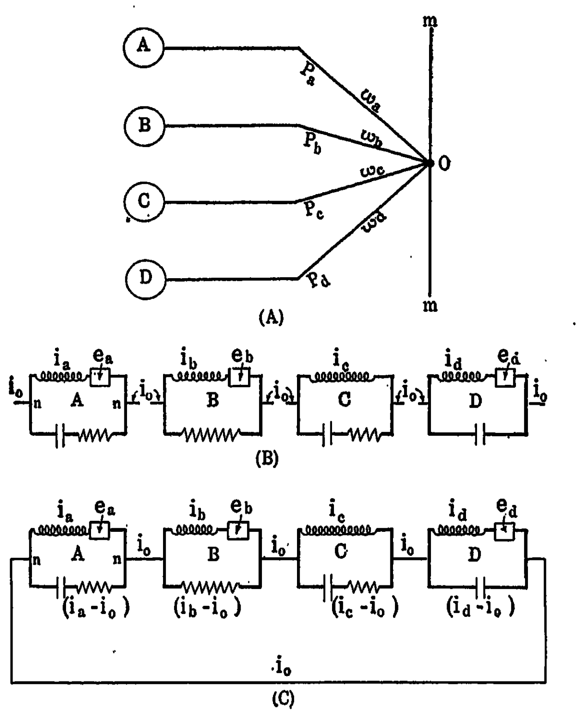

FIG. 6—SYNCHRONOUS AND INDUCTION MACHINES CONNECTED TO THE SAME BUS

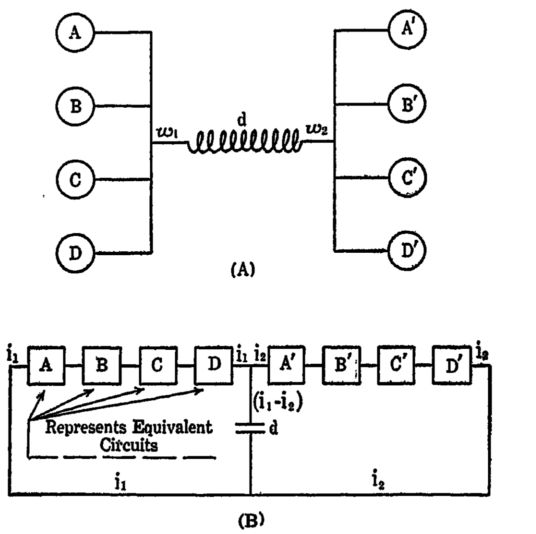

FIG. 7—EQUIVALENT CIRCUIT FOR TWO BUSSES CONNECTED BY A TRANSMISSION LINE

units A, B, C, etc. The speed of the terminal voltage—that is, the voltage at O, Fig. 6A—is represented by the current i_0. Since this must be the same for all units, the circuits must be connected in series; and since Σ torques must equal zero—the torque evidently being the voltage[6] between the junction points $n\ n$—it follows that Σ voltages must equal zero. Hence by Kirchoff's Law, the circuit must be closed, as in Fig. 6C. Therefore, *for any number of machines connected to a bus, as in Fig. 1A, the equivalent circuits of the various units should be connected in series*, as in Fig. 6C.

Thus, if the synchronous generator A were suddenly dropped from the system (by short-circuiting the points $n\ n$), the variation in the speed of the bus voltage, the instantaneous values of phase displacement, torque, speed, slip, etc. of the various machines can be read at once from the currents and voltages of the various branches. This is shown in more detail in the *Numerical Illustrations.*

Next, consider two such busses connected by a transmission line, as in Fig. 7A. The difference between the speeds ω_1 and ω_2 of the two-bus voltages is, of course, the rate at which the angular displacement between the two voltages is changing. Thus, in Fig. 7B, if i_1 and i_2 represent respectively those two speeds, then $i_1 - i_2$ would be the current to the condenser, which represents the spring-like characteristic of the line. That is, the charge on the condenser d represents the phase displacement between the ends of the line, and the current $(i_1 - i_2)$ is the rate at which it is changing. The connection must, therefore, be as in Fig. 7B. The rectangles A, B, C, and D in Fig. 7B represent the equivalent circuits as shown in Fig. 6B.

Consider next a system as shown in Fig. 8A. At the junction point or bus at G, the speed for all branches is the same, namely ω_2. There must therefore be a main series circuit, which connects the various individual circuits, and in which a current i_2 flows. Yet each bus will likewise have its own series circuit as in Fig. 6. The transmission lines a, b, and c will each be represented by a condenser which takes a current equal to the difference between i_2 and the current representing the speed of the particular bus. Thus, the component circuits are shown separately in Fig. 8B. The connections are completed by inspection, as in Fig. 8C. Thus the series circuit for each bus is shunted by a condenser representing the line which connects that bus to the common point at G, and the groups are then all connected in series.

Following the same reasoning, the equivalent circuit for the complicated system in Fig. 9A can be constructed. Here, each circle marked ω represents a bus with any number of units on it, such as in Fig. 6A. From the individual circuits shown in Fig. 9B as

6. The voltage $n\ n$ represents the electro-magnetic torque, and is obviously the impressed torque minus that consumed in acceleration:

$$T = T_m - I\,\frac{d\,\omega}{d\,t}; \text{ or, in the electrical circuit}$$

$$e_{nn} = e_a - L\,\frac{d\,i_a}{d\,t}.$$

sketched from inspection of Fig. 9A, the final connections are made as in Fig. 9C.

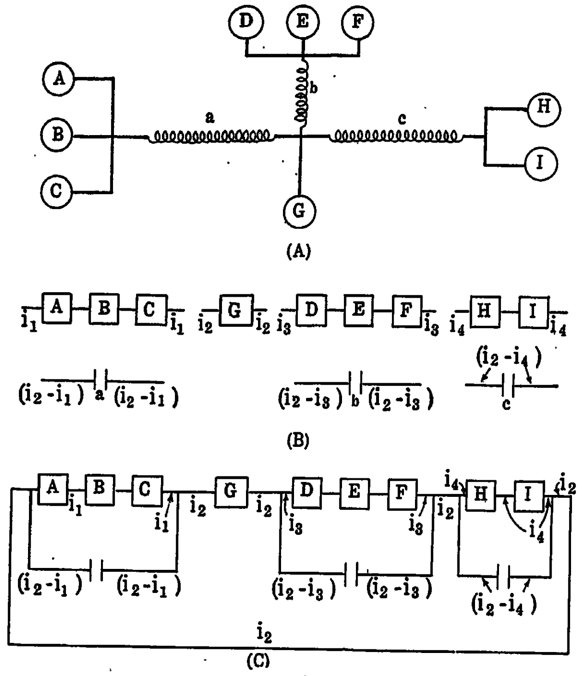

FIG. 8—EQUIVALENT CIRCUIT FOR A FOUR-BRANCH SYSTEM

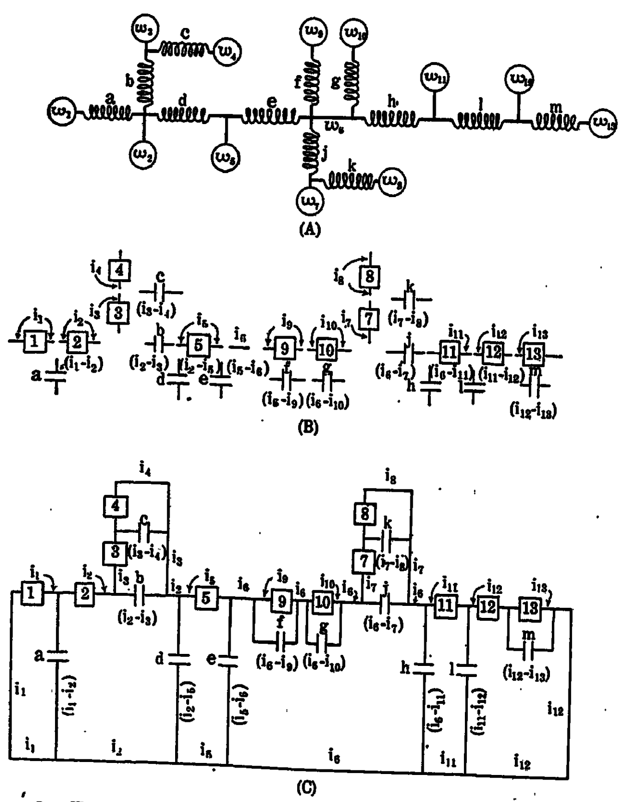

FIG. 9—EQUIVALENT CIRCUIT FOR AN EXTENDED SYSTEM

Likewise, the equivalent circuit is constructed for the network shown in Fig. 10.

Thus the guiding principles for setting up the equivalent circuits are:

1. For any number of machines connected in parallel to a bus, the equivalent circuits should be connected in series, as in Fig. 6C.

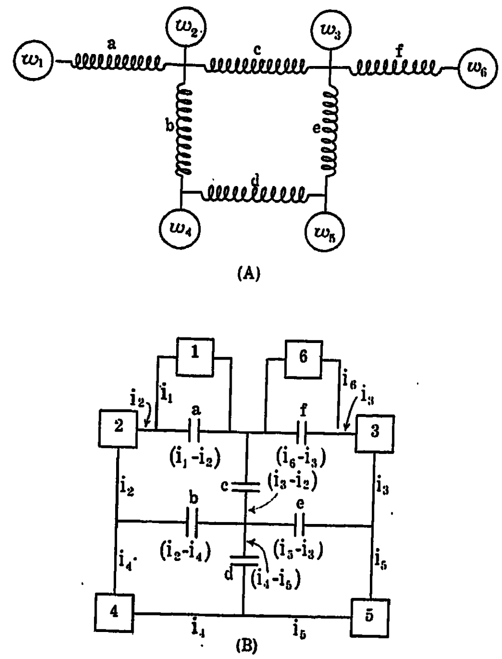

FIG. 10—EQUIVALENT CIRCUIT FOR A CLOSED SYSTEM

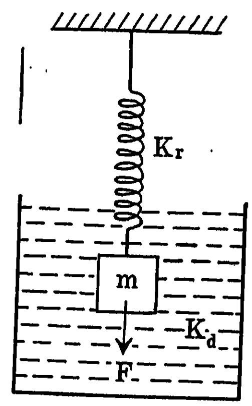
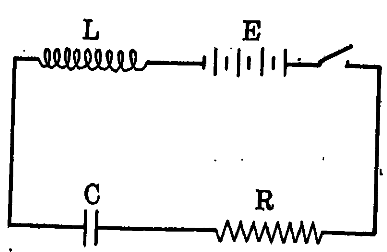


m = 0.1475 (4.75 lb.)
K_r = 0.111 ft. per lb.
K_d = 0.116 lb. per ft. per sec.
F = 4.53 lb.

a = 1.11
b = 0.0407
c = 0.0396



L = 0.164 henrys
C = 165 μf
R = 3.18 ohms
E = 120 volts

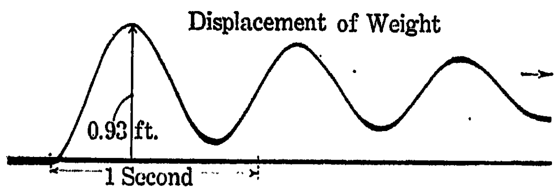
11A

2. If this bus is connected to another through a transmission line, or other inductance (the line or inductance thus being a series connection), the condenser representing the line should be connected in shunt as in Fig. 7B.

3. Condensers representing transmission lines must be always connected in such a way that the condenser current will be the difference between the two currents, representing respectively the speeds of the two buses which the line connects.

Numerical Illustrations

The differential equations, shown in connection with Figs. 1 and 2, are set up in terms of actual mechanical speeds and displacements. However, on account of the fact that the actual speeds of the various units comprising the system are different on account of the different numbers of poles, it has been found more convenient, in



11B

Fig 11—Case 1.

(A) Equivalent Circuit

(B) Oscillographic Solution

handling actual numerical examples, to reduce all quantities to the basis of a two-pole machine. This has been done in numerical examples here considered. The conversion factors are given in Table IV, Appendix B.

Case 1. Fig. 11A shows a mechanical system, consisting of a mass and spring suspended from a rigid support, having the mass m constrained to move in a damping bath. The constants of the mechanical system and the available values of L, C, and E for use in the equivalent electrical circuit are given.

The conversion factors are then obtained as follows:

$$a = \frac{\text{inductance}}{\text{mass}} = \frac{0.164}{0.1475} = 1.11$$

$$b^2/a = \frac{\text{capacity}}{\text{resilience constant}} = \frac{165 \times 10^{-6}}{0.111}$$

$$= 0.00149$$

From which

$$b = 0.0407$$

$$\text{also,} \quad \frac{a\,c}{b^2} = \frac{\text{voltage}}{\text{face}} = \frac{120}{4.53} = 26.5$$

Then,

$$c = 26.5\, b^2/a = 0.0396$$

Of the three constants, L, C, and R, if two of them are chosen arbitrarily, the third is thereby fixed. Since resistance values are easily obtained, it is convenient to take L and C as are available, and let the resistance be what is thus required.

The conversion factor for the damping constant is

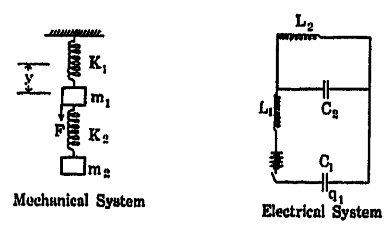
$$\frac{a}{b} = 27.3$$

Therefore,

$$R = \frac{a}{b}\, K_d = 3.18 \text{ ohms.}$$

The oscillogram, Fig. 11B, was taken of the voltage across the condenser, C, for a sudden application of voltage, E, thus giving a measure of the displacement force of the spring. The actual displacement force is obtained by dividing the voltage by its conversion factor, $\frac{a\,c}{b^2}$. The values of time for the actual system are obtained by dividing the time on the oscillogram by the factor b. Therefore, the oscillogram gives the plotted curve of either the actual displacement or the displacement force as functions of time, by merely giving it the proper scales.

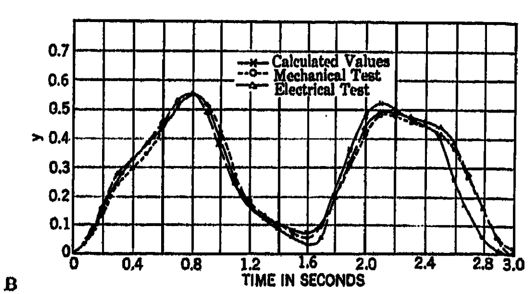
Case 2. Fig. 12A shows a composite mechanical system with its equivalent circuit. The constants for the two systems are



A

$y = .286 - .239 \cos 4.25t - .047 \cos 11t$

$q_1 = k(.286 - .239 \cos -4.25t - .047 \cos 11t)$



B

Fig. 12—Case 2

(A) Equivalent circuit

(B) Comparison of mathematical and oscillographic solutions with actual test.

Mechanical	Electrical
$m_1 = 0.218$	$L_1 = 0.246$ henrys
$m_2 = 0.1475$	$L_2 = 0.167$ henrys

Mechanical	Electrical
$k_{r1} = 0.131$ ft-lb.	$C_1 = 54.9$ microfarad
$k_{r2} = 0.111$ ft-lb.	$C_2 = 46.5$ microfarad
$F = 2.18$ lb.	$E = 264$ volts

The mass, m_1, was raised to a point 0.286 feet above its normal equilibrium position and then suddenly released. The displacement as a function of time was then calculated mathematically, and also solved by means of the equivalent circuit with the aid of an os-

cillograph. Actual test was also made on the mechanical system. The results of the three methods plotted in Fig. 12B show the remarkable agreement between the different methods.

Case 3. Fig. 13A shows a power system and its equivalent circuit. The generating apparatus consists of a shunt motor driven synchronous generator which delivers power over a transmission line to a synchronous motor. The synchronous motor is direct-connected to a (direct-current) shunt generator which furnishes power to a resistance load. The load was suddently thrown on the shunt generator. The consequent variation of power over the line was calculated mathematically, measured by means of the equivalent circuit, and obtained from actual test.

The constants used in the analysis are:

Power System	Equivalent circuit
$I_1 = I_2 = 2.78$	$L_1 = L_2 = 0.328$ henrys
$\mathfrak{J}_{r1} = \mathfrak{J}_{r2} = 0.00157$ rad/lb. ft.	$C_1 = C_2 = 27.45$ mfd.
$\mathfrak{J}_{d1} = \mathfrak{J}_{d2} = 6.3$ lb. ft/rad/sec.	$R_1{}^1 = R_2{}^1 = 16.4$ ohms
$\mathfrak{J}_r{}^3 = 0.00193$ rad/lb. ft.	$C_3 = 33.6$ mfd.

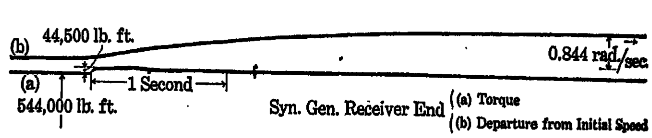
14E



14F

FIG. 14—CASE 4

(A) Equivalent circuit
(B), (C), (D), (E) and (F), Oscillographic solutions

determine the nature and magnitude of the disturbances in various parts of the system when (a) a section of the line is opened, and (b) when synchronous generator

(4) is dropped from the system. Figs. 14B, 14C, and 14D show the effect in the various units of dropping a section of line. In the equivalent circuit representing this condition, switch (2) is permanently closed and switch (1) is initially open, but is closed to produce the disturbance due to dropping a section. For this condition, the synchronous motor (3) was assumed to be carrying 400,000-kw. load, generator (1), 120,000 kw; and generator (2), 280,000-kw. Generator (4) is not connected.

Initially the system is running in equilibrium with a resultant distribution of power and displacement angles throughout the system. When the section of line is dropped, the power-angle characteristics for the system are instantly changed. For the first moment, however, the rotors, due to the inertia, remain in their original relative positions. Therefore, due to the change in power-angle characteristics of the system, there is an instantaneous redistribution and change of power and torque for the various units. Oscillograms (a), Figs. 14B, 14C, and 14D show this instantaneous redistribution and subsequent variations of torque with time for units (1), (2), and (3) respectively.

The final distribution and magnitude of power and torque is the same as the initial distribution and magnitude, since these are determined only by the governor characteristics of the prime movers and the applied load, which remains constant. However, the angular positions of the rotors with respect to each other, are different in the final condition from the initial condition since the power-angle characteristics are different. In changing from the initial to the final positions, the rotors go through certain cyclic changes in speed as shown in oscillograms (b), Figs. 14B, 14C, and 14D.

The effect of dropping generator (4) was next investigated. For this condition switch (1), in the equivalent circuit, remains open and switch (2), across which the voltage normally represents the torque of generator (4), is closed, thus eliminating the torque of generator (4) from the system. In this case the synchronous motor (3) is assumed to be carrying a 400,000-kw. load; generator (1), 100,000-kw; generator (2), 280,000-kw; and generator (4), 20,000 kw.

The consequent variations of torque in units (1) and (2) are shown in oscillograms (a), Figs. 14E and 14F, respectively. The final speed of the system is not the same as the initial speed, and the variation of speed in units (1) and (2) are shown in oscillograms (b), Figs. 14E and 14F, respectively.

Case 5. Fig. 15A shows a system consisting of an induction-motor and a shunt-motor-driven synchronous generator connected to the same bus. Fig. 15B shows variation of induction motor slip and synchronous generator torque consequent to suddenly applying full load to the induction motor. The constants shown in Fig. 15A were used in this test. The curves shown in Fig. 15B indicate that the disturbance was slightly oscillatory. To make this more pronounced, the oscillograms in Fig. 15C were taken for an induction motor which would carry full load at ½ of one per cent slip. For this condition, R_2, in the equivalent circuit, was changed to 280 ohms. Oscillogram (b), Fig. 15C, shows the speed of the synchronous generator rotor with respect to its terminal voltage and oscillogram (a) shows the torque of the synchronous generator. In this case the disturbance was decidedly oscillatory, thus showing that the combination of an induction motor with a synchronous machine is not necessarily logarithmic.

ACKNOWLEDGMENTS

The author gratefully acknowledges the valuable suggestions of Mr. R. H. Park, Professor V. Karapetoff, and Dr. A. R. Stevenson, Jr., also the assistance of Messrs. K. C. Mobarry and L. M. Best, in making tests and preparing the data.

CENTRIFUGAL GOVERNORS

Due to the inertia and sluggishness of the centrifugal governors controlling the prime movers—especially the water-wheels—additional periodic forces may be called into play in the hunting machines, which sometimes aggravate the conditions. For small changes in position, a governor may be assumed to add an input of steam or water proportional to the departure of its actual position from that corresponding to the steady load. Thus, calling this departure x, Arnold's[7] equation for a synchronous machine with an applied torque becomes

$$(J/p)\,\Omega_m\,(d\omega/dt) + W_s(\theta - \theta_m) + W_d(\omega - \omega_k) = G\,x \quad (1)$$

where G is a coefficient of proportionality equal to additional power per unit length of governor displacement[8]. Since the moving part of the governor has some inertia and is subjected both to a restoring force and to friction, its equation of motion is of the form

$$L_g(d^2x/d\,t^2) + r_g(d\,x/d\,t) + s_g x = r_0\,\omega \qquad (2)$$

In this expression, L_g is the mass of the moving part,

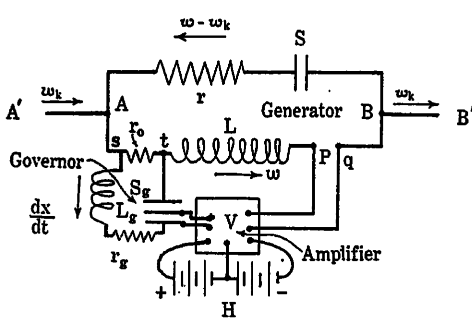

FIG. 16—EQUIVALENT CIRCUIT FOR CENTRIFUGAL GOVERNOR

r_g the friction factor, and S_g the restoring force per unit displacement. The right-hand side represents the external force, that is, the action of the generating unit, and may be assumed to be proportional to the deviation ω of its instantaneous angular velocity from the mean angular velocity ω_m; r_0 is a coefficient of proportionality. Eq. (2) is identical with Arnold's eq. (289) on p. 410, except that his x represents the total travel of the governor body from the position of zero speed, so that the departure from the mean operating position is denoted by $x - x_0$. The same applies to his value of ω.

Eqs. (1) and (2) are simultaneous differential equations of a generating unit which is hunting and the governor of which is also slowly oscillating. Both equations are of the general type

$$L\,\frac{d\,i_0}{d\,t} + S\,q + r\,i = E$$

and can be represented by two coupled, equivalent, electric circuits, Fig. 16. This equation is the familiar expression for Kirchoff's second law in a network around a closed loop containing an inductance L, an elastance S[9], a resistance r, and an external applied e. m. f. E. It must be kept in mind, of course, that in eq. (2), x corresponds to the electric charge q, and that, therefore, the current in the equivalent circuit of the governor is equal to $(d\,x/d\,t)$. The energy transformations in the governor itself are small as compared to those in the alternator, and the governor acts merely as a relay—controlling energy input into the prime mover. Therefore, in the equivalent electric circuit the storage battery H is shown, the energy of which may be added at will between the points P and q, which correspond to the disturbing e. m. f. e_a in Fig. 6C. An amplifier, V, is connected with its input side in the governor circuit and the output side in the alternator circuit.

In eq. (1), the term $G\,x$ on the right-hand side represents the voltage between the points P and q, proportional to the instantaneous displacement of electricity, x, in the governor circuit. For this reason, the input leads to the amplifier are shown connected across part of the condenser S_g. The elastance of this part is so chosen, that the voltage across it, when properly amplified, will give the required voltage, G, on the output side.

In eq. (2), the right-hand side represents the drop of voltage due to the current ω through a resistance r_0. This resistance is shown connected between the points s and t of the inductance branch of the main circuit. Since the currents and the voltages in the governor circuit are much smaller than those in the main generator circuit, the resistance r_0 is of the nature of an ammeter shunt. This means that the voltage drop across $s\,t$ is small in comparison with that across $A\,B$, and the current $d\,x/d\,t$ is small in comparison with ω.

Since the main circuit in Fig. 16 is practically identical with that shown for the individual unit in Fig. 6C, the other connections as shown in Fig. 6C still hold true when some or all of the machines in parallel are controlled by centrifugal governors.

When the action of the gate, controlled by a centrifugal governor, causes a surging motion of the whole column of intake water, the inertia of this column and the elastance of the surge tank may have to be taken into consideration. This can be done by including in the circuit of the battery H, Fig. 16, some inductance, resistance, and elastance, connected somewhat as in the equivalent circuit of the generator itself.

Appendix B

CONVERSION FACTORS FOR REDUCING QUANTITIES TO THE BASIS OF A TWO-POLE MACHINE

Since power systems, in general, are comprised of multipolar machines having unequal numbers of poles, the relation between mechanical and electrical speeds

7. *Die Wechselstromtechnik*, Vol. 4, Second Edition, page, 381.
8. *Die Wechselstromtechnik*, Vol. 4, Second Edition pp. 415 and 418.
9. An elastance is a reciprocal of a capacitance; see V. Karapetoff, "The Electric Circuit," page 148.

for the various units is not uniform. For the sake of uniformity and convenience in numerical examples, it is advantageous to substitute for the respective units an equivalent two-pole machine. The synchronous electrical speed of the system then becomes identical with the synchronous mechanical speeds of the various units.

If p is the number of poles of any given unit, the speed of the equivalent two-pole machine must be $p/2$ times as great since the the electrical speed or frequency must remain the same.

Also since torque is inversely proportional to speed for a given power, the torque of the equivalent two-pole machine will always be $2/p$ times the torque of the actual machine.

Since the speed for the two-pole unit is $p/2$ times as great as the actual mechanical speed, it is evident that the acceleration for the equivalent machine will also be $p/2$ times as great as the actual mechanical acceleration. Now in general, the torque consumed in acceleration is $T = I\,a$.

Or, $$I = \frac{T}{a}$$

where I is the moment of inertia and a is the acceleration produced by the torque T. The conversion factor for I is then evidently the ratio of the factor for torque to the factor for acceleration, or $4/p^2$.

The mechanical angle traveled through in a given time will be proportional to the speed or $p/2$ times as great in the equivalent two-pole machine as for the actual unit.

Let P_0 be the power required to produce a displacement of one electrical radian in the synchronous machine. Since the conversion factors are to reduce all quantities to the basis of a two-pole machine, and P_0 is already expressed in these terms, the factor for it is unity.

Following the foregoing reasoning, the factor for converting the actual resilience constant

$$\mathfrak{J}_r = \frac{\text{Mechanical displacement}}{\text{torque required to produce it}}$$

to a two-pole basis, is $p^2/4$.

Likewise the factor for converting the damping constant $\mathfrak{J}_d$, is $4/p^2$.

The conversion factors are tabulated in Table IV.

TABLE IV

Quantity for Actual Machine		×	Conversion Factor =	Quantity for Equivalent Two-Pole Machine
Mechanical torque	$\mathfrak{J}$		$2/p$

Discussion

R. E. Doherty: Anyone who has wrestled with differential equations in attempting to solve those of higher order must certainly be impressed with the possibility of having an electric circuit solve them and an oscillograph plot the solution. This is precisely what Mr. Nickle's scheme does.

The extent to which it has been developed in this paper is, in my opinion, only a beginning, touching as it does only those cases in which the phenomena can be represented by circuit elements which are constant. However, the scheme is not limited to such cases. The method is perfectly general and applicable to any problems for which circuit elements of proper characteristics are available.

Regarding its present possible application to problems involving constant circuit elements, it should not be inferred from the paper that it is applicable only to problems of power transmission; rather, it applies to many other problems involving mechanical oscillation, for instance, the flywheel problem of synchronous machines connected to reciprocating apparatus, short-circuit forces in busbars, etc. Such problems are beautifully solved by this method.

I wish to call attention, also, to its educational value in drawing out the parallel between various physical phenomena. In this, it is of great value and I commend it to the attention of educators.

R. D. Evans: In regard to the application of Mr. Nickle's work to the solution of the problems which are facing the industry at the present time—such as the stability problem—there are a number of points which I would like to discuss. The method as described in the paper is of limited application in the study of stability, for the reason that the fundamental assumptions involve power relations proportional to the angle of phase difference between e. m. f.'s instead of a trigonometric function of the angle. Stability is of importance in the vicinity of the limit, and for this condition the assumption that the power is directly proportional to the angle is entirely too crude for practical application.

The method described by Mr. Nickle has application in the determination of the hunting condition rather than for the stability condition where pull-out may occur. For the condition of hunting, the power changes in almost direct proportion to the angle, and the approximation that the power is directly proportional to the angle is sufficiently accurate for the purpose.

It is possible that Mr. Nickle's methods may be extended, not to solve the stability problem as a whole, but to solve a particular part. For example, it may be possible that his method may be applied to the receiving network of a transmission system in order to find a simple equivalent. Such a possibility seems likely because the power limits of the individual parts of the receiving network are relatively high in comparison with the power limits of the transmission network. Consequently the phase difference is small and the approximation assumed in this paper is sufficiently good for the purpose Having found a simple equivalent of a receiving network, the problem of determining the stability would be much simplified and could be handled analytically from this point.

We have been working along the same general lines, but in a somewhat different manner. Instead of converting the electromechanical transients to an electrical transient, we have sought to convert the electro-mechanical transients to a transient of a mechanical system. One of my associates, Mr. Griscom, has investigated a mechanical system which avoids the limitation in Mr. Nickle's paper, due to the power being proportional to the angle of phase difference. Mr. Griscom was able to represent the trigometric function accurately. In the original form of the method, there were limitations due to the inability to represent losses with absolute accuracy.

These comments are made merely to point out the limitations in the method so far developed and described, and with the

hope of stimulating further work along these lines, for the electromechanical problem which Mr. Nickle has studied is one which in general cannot be solved analytically, but must involve either a solution of the type which Mr. Nickle has presented or involve a method of simplifying networks, so that the system, as a whole, will be sufficiently simple to handle analytically.

C. A. Nickle: The differential equations for any electrical circuit are linear if the values of inductance, capacitance, and resistance remain constant. Evidently, such electrical circuits offer a rigorous solution for only those systems which may themselves be represented by linear equations.

The equations for a transmission system are not linear and hence the method cannot be used for values of power near the power limit. However, for values of power well below this limit, such a system may be represented for all practical purposes by linear differential equations and the equivalent-circuit method may be used. In this way the effect of various types of disturbances, such as dropping a generator, opening a line section, adding load, etc., may be studied. The relative severity of different types of disturbances, the effect of various physical constants on the behavior of the system, etc., may be investigated.

It should be realized, however, that the investigation of power-transmission problems is only one of the many possible applications of this method of solution. For instance, the sustained oscillation of synchronous machines connected to reciprocating apparatus may be easily and accurately determined by this method.

As already emphasized, the use of constant values of inductance, capacitance, and resistance limits the method to systems represented by linear differential equations, but the use of circuit elements which vary in accordance with certain prescribed laws is quite within the range of possibility, thus making the method applicable to systems which are not linear.

The Klydonograph and Its Application to Surge Investigation

J. H. COX[1] and J. W. LEGG[1]

Associate, A. I. E. E. Associate, A. I. E. E.

Synopsis.—In the past few years the need of a device for recording voltage surges on transmission lines has been felt more and more. Realizing this need, J. F. Peters, in the fall of nineteen twenty-three, developed the klydonograph which utilizes the Litchtenberg figure to record the characteristics of transient voltages. The principle of the instrument and practical connections to a line are discussed. The results obtained in the field from four investigations are given.

Parts II and IV describe the first experimental model of the klydonograph which uses a stationary glass photographic plate in removable plateholders with a moving electrode, and the commercial type of klydonograph which uses a day-light loading roll film of sufficient length to last seven days. This latter model has three electrodes for connection to a three-phase line.

* * * * *

I. Principle and Characteristics

SINCE the beginning of high voltage transmission the question of the nature of transient voltages on transmission systems has been a troublesome problem. Many troubles have been attributed to surges, but without positive evidence of their existence. However, there is considerable evidence that transient overvoltages of short duration do exist on transmission lines and information regarding them is very desirable. There has been developed a considerable amount of theory regarding these transients but very little verification of this theory by test has been produced, due to the absence of a satisfactory means of measurement. Heretofore, the spark gap has been the principal means of measurement. It was found that the spark gap had considerable time lag when the voltage in excess of its flashover value was small. Other objections to the spark gap for the measurement of transients are well known. Various other devices that have been tried had practically the same objections; that is, they had time lag, were not graphic, indicated only one value, introduced hazards to the line or were excessively expensive.

Principle. The klydonograph[2] was the successful culmination of the effort of J. F. Peters and his assistant, W. L. Teague, to develop a satisfactory surge recorder, one that would give a continuous graphic record of detailed information regarding magnitude, time of day, polarity, steepness of wave front, direction of travel, and whether or not the surge was oscillatory. In producing this instrument a phenomenon was utilized that has been known for a century and a half. In 1777, Dr. G. C. Lichtenberg first observed that when a condenser was discharged onto a terminal in contact with a plate of insulating material such as ebonite between it and a grounded metallic plate, and particular kinds of powder, such as flour of sulphur, were sprinkled on the insulating plate, the powder would arrange itself about the position of the terminal in a distinctive and consistent manner. The powder could be applied either before of after the discharge. Figures thus formed are called Lichtenberg figures.

Since the original observations, there has followed a long series of investigations on these figures. In 1888, J. Brown and E. Trouvelot discovered that these figures could be produced by replacing the insulating plate with a photographic plate, the emulsion being in contact with the terminal. The plate, of course, had to be kept in a dark box. The glass plate acted as the insulating material and the emulsion, when developed, replaced the dust. It was found that figures thus produced were more definite and clean cut than those produced by the use of dust. The most recent and most complete exposition of the Lichtenberg figures was that by P. O. Pederson of Copenhagen, Denmark, in a paper for "Det Kgl. Danske Videnskabernes Selskab, 1919." This paper carefully analyzes the characteristics of the figures and gives a number of curves of these characteristics. However, the curves are small, only indicate the general shape of the variations, and are not suitable for calibration. The method used by Pederson was that developed by S. Mikola in 1917.

Considerable investigation has been made, but with little success, to determine the nature of the phenomena that causes these figures. No attempt was made in the development of the klydonograph to explain the phenomena, but the work was confined to a study of the characteristics of the figures for their use in gaining information regarding surges. As far as was known, Lichtenberg figures had been used only in an academic way and never for the measurement of transients as such.

The essential elements of the klydonograph are shown in Fig. 1. The form in which these were assembled for the laboratory work is shown in Fig. 2. This laboratory instrument had six terminals and took

1. Both of the Westinghouse Electric & Mfg. Co.

2. The word "Klydonograph" was suggested by Dr. Roscoe M. Ihrig of the Carnegie Institute of Technology. It is derived from two Greek words "Kludon" and "Graphos." Kludon means "billow" or "wave," and a related adjective means "surging" or "dashing." Graphos means a writing. Thus the Klydonograph means an instrument for recording surges.

The Klydonograph, J. F. Peters, *Electrical World*, April 19, 1924.

Presented at the Annual Convention of the A. I. E. E., Saratoga Springs, June 22-26, 1925.

a 5 in. by 7 in. plate. It is not suitable for commercial work, as it is not graphic. For this work, it was found that any plate of high photographic speed was satisfactory. No work was done using dust figures.

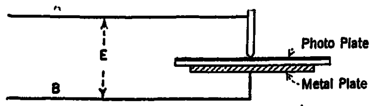

FIG. 1—ELEMENTS OF THE KLYDONOGRAPH

Characteristics. When a voltage above the critical voltage is impressed between A and B of Fig. 1, and the plate developed, a figure will be found surrounding the

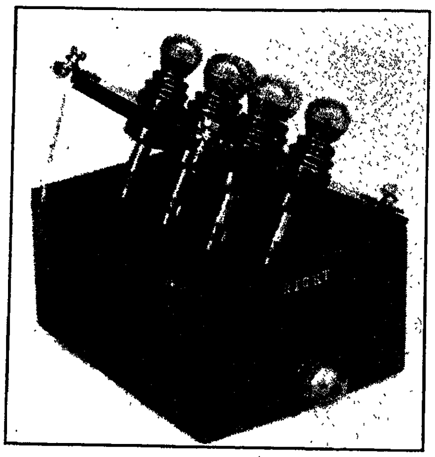

FIG. 2—LABORATORY KLYDONOGRAPH

spot where the terminal has been in contact. The critical voltage is approximately 2.0 kv., below which, at atmospheric pressure, no figure is produced. The

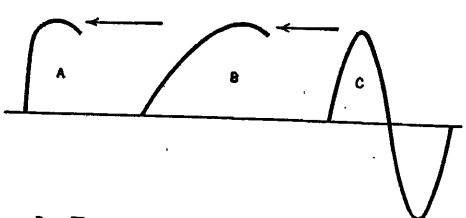

FIG. 3—TYPICAL WAVES: (a) ABRUPT, (b) SLOPING, (c) ALTERNATING

figures consist of branches, or lines, emanating uniformly from the center. They maintain this form up to about 18 kv., when, in addition to the uniform branches, main trunks extend out from the center and in turn act as emission points for other branches. These trunks do not form in a consistent manner as do the branches. If the voltage is further increased a point will be reached where a visible spark will occur and the entire plate will become exposed. If the voltage impressed is unidirectional there will be a striking difference between the figures produced by positive and negative potentials. In the case of an oscillating voltage the two will be superimposed. By the figures one may also distinguish between an abrupt-front surge, such as indicated in Fig. 3A, and a tapered-front surge, as indicated in Fig. 3B. Figs. 4 and 5 show a positive and a negative surge, respectively, having a front as abrupt as could be produced by ordinary means in the laboratory. Figs. 6 and 7 show a positive and a nega-

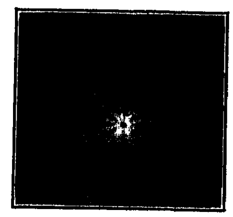

FIG. 7—NEGATIVE SURGE, FIVE-MICROSECOND FRONT

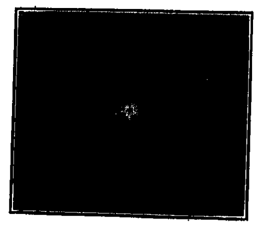

FIG. 8—POSITIVE SURGE, 200-MICROSECOND FRONT

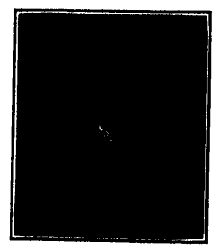

FIG. 9—NEGATIVE SURGE, 200-MICROSECOND FRONT

FIG. 10—POSITIVE SURGE, ABOVE RANGE OF INSTRUMENT

FIG. 11—NEGATIVE SURGE, ABOVE RANGE OF INSTRUMENT

tive surge, respectively, having a front of five microseconds; that is, it required five-millionths of a second to rise from zero to its maximum value. This corresponds to a traveling wave having a front of one mile on a transmission line. Figs. 8 and 9 show similar surges having fronts of 200 microseconds or 40 miles. Distinct differences in the figures formed by these three lengths of wave front can be noticed. Figs. 10 and 11

show a positive and a negative surge that were above the range of the instrument. Fig. 12 shows a figure produced by an alternating potential such as in Fig. 3c.

The paper by P. O. Pederson goes into considerable detail regarding the make-up of the figures and their variations due to differences in plate thickness and pressure of surroundinggas. In this development, these

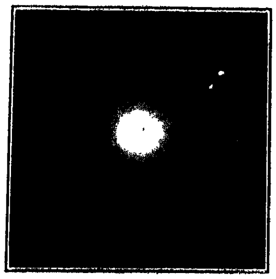

FIG. 12—ALTERNATING VOLTAGE

phases were investigated only to the extent of determining that the figures were practically constant within the range of atmospheric pressure in air and of thick-

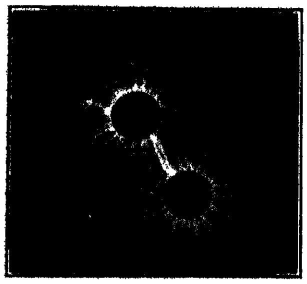

FIG. 13—POSITIVE FIGURES, 30 SECONDS BETWEEN SURGES

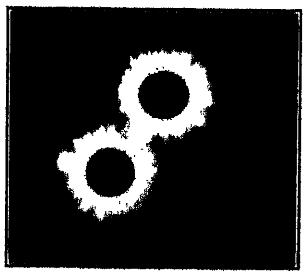

FIG. 14—NEGATIVE FIGURES, 30 SECONDS BETWEEN SURGES

nesses of commercial photographic plates. Further special tests were made and it was found that, so far as could be detected, the figures were identical whether

FIG. 15—POSITIVE FIGURES, TERMINAL MOVED BETWEEN SURGES

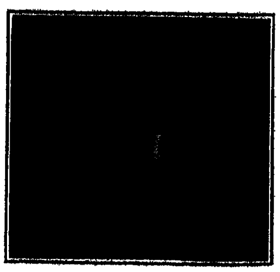

FIG. 16—NEGATIVE FIGURES, TERMINAL MOVED BETWEEN SURGES

produced in fairly dry or in saturated air, and whether the plates were developed immediately or after a lapse of several days. According to Dr. Pederson, in order to form a figure the voltage must be impulsive so as to produce an intense field on the surface of the plate. It was found that a 25-cycle wave would produce a figure of the same size as a wave of short front. However, if a d-c. potential was gradually applied, the figure produced was peculiar in shape and did not confrom to the calibration curve in size.

Tests were made to determine whether or not one application affected the plate to succeeding applications. The rays or branches of a single figure never cross. It was suggested that if one surge were recorded and a comparatively short time later another surge appeared, the figures might not overlap and the second surge would make no impression. Tests were made

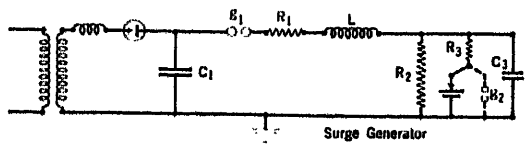

FIG. 17—NETWORK USED IN LABORATORY

which proved that one impression has no effect on succeeding records. If two surges are impressed simultaneously on adjacent terminals, the figures will not overlap. If a surge is applied on the position of a previous surge it superimposes its figure exactly as if there had been no previous figure and the rays of the two figures cross each other promiscuously. In this manner a succession of figures merely increases the density and with a large number the spot becomes black. This is what happens in an a-c. figure. Figs. 13 and 14 show positive and negative surges, respectively, where one surge was impressed and a few seconds later a surge was impressed on the adjacent terminal. Figs. 15 and 16 show similar surges where there was a similar interval and each terminal was in contact with the plate only when the surge was im-

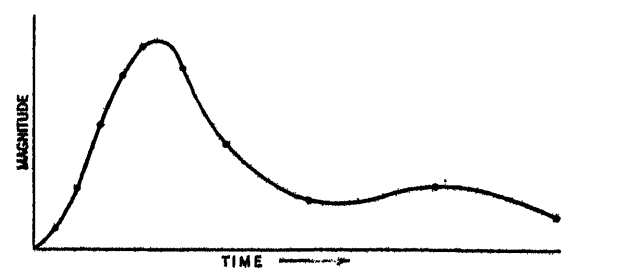

FIG. 18—TYPICAL SURGE PRODUCED BY NETWORK OF FIG. 17

pressed. Further, the size of each succeeding figure was determined only by the applied voltage. This was checked by applying surges of equal values a various number of times, one to six, on the six terminals of the instrument. The figures were of the same size and only differed in intensity.

Calibration. Fig. 17 shows the network used in the laboratory as a surge generator in the development of the klydonograph. Fig. 18 shows the shape of a typical surge as calculated from the constants of the network. By varying the constants of the network a surge of any desired wave shape could be produced. It was found

to be no easy matter to obtain surges of the desired characteristics. The greatest trouble was encountered with the reflections of the initial traveling wave. Before the condenser, c_3, at the end of the network, was added, when the sphere-gap sparked over a wave would proceed out through the series inductance and when it hit the klydonograph it would reflect with increased voltage. The klydonograph itself forms a small condenser so an oscillation would be set up in the circuit. The klydonograph would record these oscillations. Further, due to the reflection the klydonograph would record a higher voltage than the setting of the spark-gap. By placing the condenser c_3 in parallel with the klydonograph the initial wave would be absorbed. This would be reflected but in this case since the surges were tapered, it did no harm and would join with the principal part of the surge in bringing the voltage up to the proper value. However, it was found necessary to place resistance R_3 in series with the klydonograph to critically damp the loop consisting of leads, klydonograph and c_3 to prevent small reflections at the plate. This did not disturb results as a non-inductive resistance was used and the voltage drop was negligible since the current was very small. It was interesting to notice that a sphere-gap would not indicate these reflections but the klydonograph would. To obtain the desired setting the klydonograph was removed and gap g_2 inserted and set at the desired voltage. Gap g_1 was then varied until g_2 would just spark over at the breakdown of g_1. Gap g_2 was then replaced by the klydonograph, and leaving g_1 as set, a series of figures were made.

The diameter of the figure is a measure of the magnitude of the surge. Positive and negative surges have quite different calibrations, a positive figure being considerably larger for the same voltage. Since the positive is the larger, the a-c. calibration is the same as the positive. All the work for the calibration curves was done with five-microsecond and 200-microsecond surges. Tests were made which indicated that for a surge with a front as long as 5 microseconds the time lag of the measuring sphere-gap was negligible. In addition to this, the characteristics of the surge generator used gave a surge with a comparatively flat top. It was found that the calibration was the same for unidirectional surges of both these wave fronts of each polarity as well as for a 60-cycle and a 25-cycle a-c. wave. It was realized that even with no coil inserted, the inductance of the leads and the time lag of a sphere-gap would give a slight taper to the wave. The figures shown as abrupt-front surges were as abrupt as could be made with ordinary methods. They were made with no inductance between the spark-gap and klydonograph except that of a short lead. It takes a certain time for a sphere-gap to break down and become highly conductive, so it was felt that surges thus produced could not be called absolutely abrupt nor be depended upon to be of the same degree of steepness. They were, therefore, not used in calibration work.

It was found in calibrating that the radius of a figure made at a setting of the generator would vary as much as 20 per cent from the average reading of the same value but most of them were within 10 per cent of the average. This would not seem to be very accurate at first glance, but it is maintained that the variation was impressed in the voltage due to inaccurate setting of the spark-gap and inaccuracies in the method used, and not in the figure made by the klydonograph at a given voltage. The network would be set for a given voltage and condition of surge. The voltage was tested in the position of the klydonograph by a sphere-gap. A series of pictures would then be taken and the network changed to some other value. The curves were made up from the results of a great many settings for a given value. These settings were made on different days over months and it is impossible to duplicate such a set-up with exactness. The basis for attributing the error to set-up rather than klydonograph is the fact that for a single setting the variation between the figures was exceedingly small. To test this quality further, surges were thrown on six leads connected to the six terminals of the test instrument, simultaneously, and in practically every case there were no variations that could be measured. In the few cases where there were measurable variations, these variations were very slight.

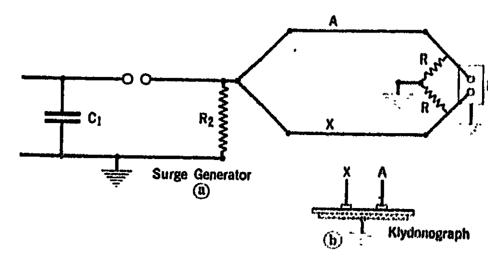

FIG. 19—ARRANGEMENT USED TO MEASURE SHORT-TIME INTERVALS
(a) SURGE GENERATOR (b) TWO-TERMINAL KLYDONOGRAPH

Rapidity. Since surges may be of extremely short duration it was highly important that the klydonograph be a rapid instrument. Many tests were made to determine the speed of formation of the figures. The diagram of the set-up used to obtain these data is shown in Fig. 19. This merely consisted of a circuit which discharged a condenser through a sphere-gap into two open-wire lines which were shunted to ground by a high resistance. The lines A and X were connected at the far end to a special klydonograph having two ⅜-in. terminals in contact with the plate at a short distance apart. The time lag of the sphere-gap used to discharge the condenser played no part as the data obtained was of conditions after the gap had broken down. When the sphere-gap broke down a surge was impressed on the two lines simultaneously, and would proceed as a traveling wave at approxi-

mately the speed of light. If the lines were of equal length, the wave would arrive at the ends at the same time. Figs. 20 and 21 show positive and negative figures, respectively, made with equal length lines. The division line between the two figures was distinct and its action positive in that its position was consistent with repeated trials. Tests were then made having one line longer than the other. Figs. 22, 23, and 24 show surges impressed on unequal lines. Fig. 22 is for a positive surge with $A = 30$ ft. and $X = 50$ ft. From the rate of propagation of a surge on an aerial line this difference of 20 ft. represents a time interval of 2 by 10^{-8}, or twenty billionths of a second. It is to be noticed that the surge from the shorter line took possession of more than one-half the space between the figures. Fig. 23 is for a positive surge with $A = 50$ ft. and $X = 140$ ft. This difference of 90 ft. corresponded to a difference in time of the arrival of the wave at the instrument of 9 by 10^{-8} seconds or ninety billionths of a second. It is noted here that A is practically fully developed when the wave arrived at X, so that the figure became nearly complete in ninety billionths of a second. Tests were made varying the difference in

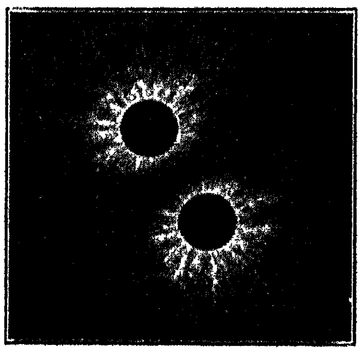

FIG. 20—POSITIVE FIGURES IMPRESSED OVER EQUAL LINES $A = X$

line lengths and the speed of the figures was found to be consistent. Fig. 24 is for a negative surge with $A = 30$ ft., $X = 60$ ft. The negative figures were found to be the slower by about five times. This is evident from a comparison of Figs. 22 and 24. However, either is amply rapid for the purpose of recording practical surges.

It was interesting to note the evidence of the tapering of the wave front as it traveled down the line even in such short distances as 100 ft. Fig. 20 shows the two figures made with lines of equal length to be identical in form. On the other hand, Fig. 23 shows the figure produced at the end of the longer line as indicating, by its form, a longer wave-front than the other.

Since it takes time for a spark-gap to spark over and become highly conductive, the surges were somewhat tapered, and if the lines were short the reflection of the foot of the wave would return from the shorter line and disturb results. In fact this would sometimes cause the figure to form on the more distant terminal first. Therefore, the lines had to be long enough so that the complete wave would arrive before the reflected wave of the shorter line disturbed the principal wave. When a wave strikes the open end of a line, it theoretically doubles. The voltage was found to increase at the end of the line but did not double in value except where the line was of considerable length. Lines could not be made long enough so that the entire wave front could

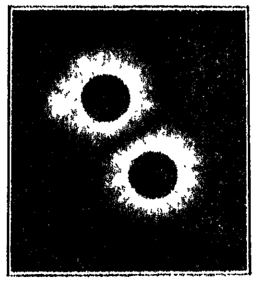

FIG. 21—NEGATIVE FIGURES IMPRESSED OVER EQUAL LINES $A = X$

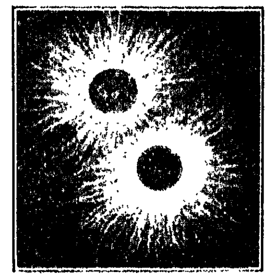

FIG. 22—POSITIVE FIGURES IMPRESSED OVER UNEQUAL LINES $A = 30$ $X = 50$

start before the reflected foot of the wave would return and complicate the wave. In order to cut down this reflection as much as possible, a resistance equal to the surge impedance of the line was placed in parallel with the klydonograph. This was found to absorb the wave with practically no reflection and the true surge would be recorded with no increase in voltage. Before this grounding impedance was added, it was interesting to note that a sphere-gap at the end of the line, while it indicated a rise in voltage would not indicate the full

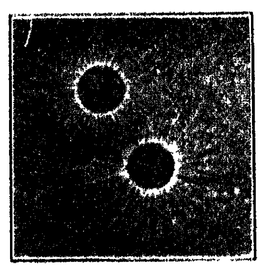

FIG. 23—POSITIVE FIGURES IMPRESSED OVER UNEQUAL LINES $A = 50$ $X = 140$

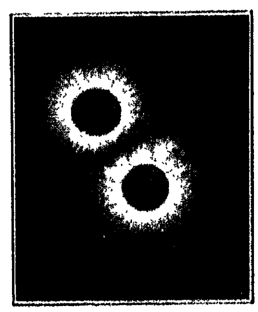

FIG. 24—NEGATIVE FIGURES IMPRESSED OVER UNEQUAL LINES $A = 30$ $X = 60$

value of the reflection as recorded on the klydonograph. In the case of a long line, the klydonograph indicated practically double voltage.

Extensive tests were made by Pederson to measure the speed of formation of the figures, that is, the rate at which the figures grow from the center outwards. This he found to vary somewhat with the distance from the center and with the voltage, but to remain of

the same order of magnitude. He gives the following values:

Speed at 8 kv. positive — 4 by 10^7 cm. per sec.
" " 8 kv. negative— 1 by 10^7 cm. per sec.
" " 15 kv. positive—6.5 by 10^7 cm. per sec.
" " 15 kv. negative—2.8 by 10^7 cm. per sec.

Special Applications. The Lichtenberg figure promises, in addition to its use in surge investigation on transmission systems, to be a valuable aid in special tests both in the laboratory and field. It can be used in the measurement of exceedingly small time intervals

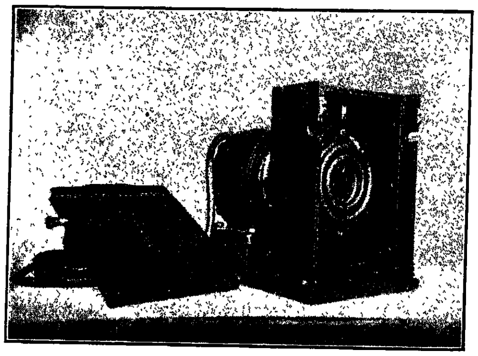

FIG. 25—SYNCHRONOUS KLYDONOGRAPH

wherever a capacity of the order of 10^{-11} farads is negligible and the voltage is above 2.5 kv. Some work has been done by P. O. Pederson on the time lag of a spark-gap. There has not been time, since the development of the klydonograph, for much special investigation, using it as an instrument. Fig. 25 shows a

FIG. 26—FIGURE PRODUCED BY SYNCHRONOUS KLYDONOGRAPH

synchronous klydonograph which was developed for the purpose of separating the positive and negative figures of an a-c. wave. Fig. 26 shows a typical picture produced by a 60-cycle wave.

Electrostatic Potentiometer. To be applicable to transmission systems in general the instrument must have a wide range of voltage. The range of the instrument itself is from 2.5 kv. to 18 kv. Since the instrument is an exceedingly low current device, it can be connected by means of an electrostatic potentiometer to lines of practically any voltage without introducing an insulation hazard. An electromagnetic multiplier is, of course, out of the question, since there must be no time lag. Fig. 27 shows a satisfactory method of connecting the klydonograph to a line. The lower ring in this set-up will maintain at all times the same

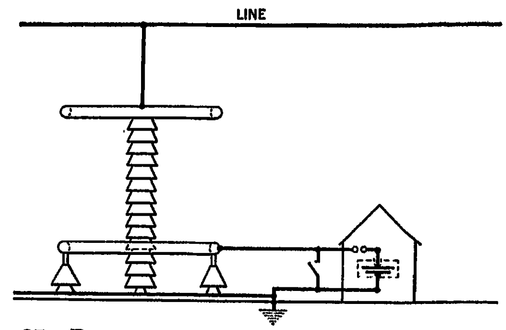

FIG. 27—DIAGRAM OF ELECTROSTATIC POTENTIOMETER

proportion of the potential on the upper ring. A klydonograph connected in this manner will record figures giving the magnitude and polarity of the surges.

A gap in series with the instrument may be included as shown, or left out as desired. If included there will be no record except in case of a surge the voltage of which is in the same ratio to normal as the setting of the gap is to the normal voltage on the lower ring. If no gap is used, there will be a uniform band on the plate corresponding in width to the diameter of the positive figure at the normal voltage on the lower ring. A surge figure will then be superimposed on this band. The width of the band will also indicate wide variation in line voltage. Whether or not the instrument is operated with a series-gap, the potentiometer must be calibrated with the gap closed. The reason for this is that the capacity of the instrument, while small, cannot be ignored in comparison with that of a practical low potential ring. The voltage on the lower ring after the gap breaks down is not the same as before since there is a division of charge.

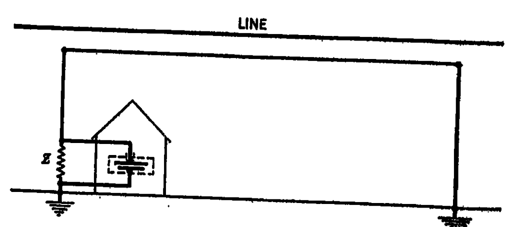

FIG. 28—DIAGRAM ON ANTENNA

Antenna. While some idea of the steepness of wave front can be gained from the appearance of the figures obtained on the potentiometer instruments, this is extremely approximate. Fig. 28 shows a means of connection that will give the steepness of wave front more accurately. This consists of running a wire parallel to the transmission-line conductors as close as is consistent with the insulation requirements,

grounding one end solidly and the other end through a high impedance. The klydonograph is connected across this impedance and if the impedance is high compared to the impedance of the antenna loop itself, the klydonograph will measure any voltage above 2.5 kv. which may be induced in the loop. This antenna loop will have a certain mutual inductance in relation to the various conductors of the transmission line. At a given distance the length is varied to give the desired amount. The voltage induced in the antenna loop will be proportional to $d\,i/d\,t$ on the transmission line; that is, it is proportional to the steepness of the current wave. Under traveling wave conditions the current and voltage waves are absolutely inseparable. The current is always equal to the voltage divided by the surge impedance of the line and the wave shape is the same. Therefore, the steepness of the voltage wave front $d\,V/d\,t$ can be calculated by the relation

$$d\,V/d\,t = \frac{Z_0}{M}\,e \quad \text{where}$$

e = Voltage induced in antenna loop
M = Mutual inductance between loop and line conductor
Z_0 = Surge impedance of line conductor calculated with respect to the ground

By a comparison of the polarity of simultaneous readings on the klydonograph connected to the line through the electrostatic potentiometers and that connected on the antenna, the direction of travel can be determined. That is, a surge of a particular polarity will induce a potential of one polarity in the antenna if traveling in one direction, and of the opposite polarity if traveling in the other direction. The direction is readily determined from an examination of the connections. Thus, magnitude and polarity are obtained directly from the potentiometer klydonographs, steepness of wave front from the antenna klydonograph, and the direction of travel from a comparison of the polarity of the two.

II. Preliminary Field Model, Plate Type

A *time component* must be added to the camera already described before the same is effective in obtaining data on disturbances in transmission systems. To obtain a time component, the electrode must move relative to the plate or photographic film. Either the plate may move and the electrode remain at rest, or the electrode may move while the plate remains at rest. Each of these two cases has its advantages and its disadvantages. If the plate is the moving element, the electrode capacity to ground may be kept a minimum, but the case must be large enough to clear the carriage of the moving plate. The apparatus as a whole is cumbersome and is not readily loaded without taking a large part of it into a dark room.

Stationary Plate. The first field model, Fig. 29, was made with a stationary plate in a removable holder, enclosed within the same light-tight cabinet with the clock-driven electrode. The holder was of the single-plate type having a stiff metal bottom. Above this metal bottom was a sheet of soft felt, cut away at the center so as to press a very thin disk of hard-sheet-metal against the under surface of the active part of the photographic plate. The metal disk was grounded through the plate holder bottom, and did not extend to the edges of the photographic plate. Thus, a uniform capacity was assured, and sufficient insulation between the electrode and ground. A number of these removable plate-holders were provided for each recorder.

Clock Driven Electrode. A one-day clock was used in most recorders, driving the electrode in a 7-in. circle, one revolution in 24 hours. A few instruments were equipped with 7-day clocks making one revolution in 168 hours. The electrode was mounted vertically near the edge of a light disk of insulating material, having a wire-collector ring on its periphery. The lead-in terminal, passing through an insulating bushing

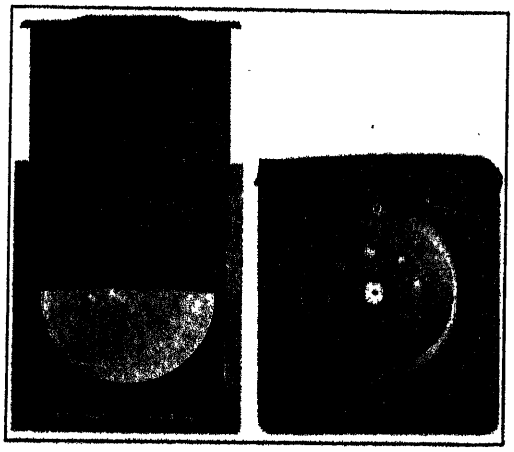

Fig. 29—Plate-Type Klydonograph, Showing Rotating Electrode and Hour Circle

in the case, had a brush on the bottom end which bore on the collector and thus carried the potential to be measured to the electrode proper. This electrode was free to move up and down and pressed on the sensitive side of the photographic plate with its own weight only.

Time Locating Device. In order that the time at which each surge occurred might be known by a glance at the finished photographic plate, a photographic template was prepared with opaque background and transparent dial and figures. All klydonograph plates were exposed to light with this template over them, so that when the plate was developed a circular scale, marked in 24 hours with "Midnight" at top and "Noon" at bottom, appeared. An hour circle on the electrode disk was also graduated into 24 hours. If this was set correctly before starting the test, by slipping the friction clutch on the clock shaft until the figures on the disk corresponded to true time, the klydonograph figures would appear after development

in their proper time relation with the scale on the plate.

The instrument was inverted to set the electrode disk through a large hole in bottom of the case, and before turning the instrument right side up the plate holder was inserted. The removal of the rubber slide from the plate holder permitted the electrode to drop to the sensitive surface of the photographic plate, and thus be in condition to take a klydonogram. After a 24-hour test, the instrument was again inverted, the rubber slide replaced, and the plate holder removed.

III. Field Experience

Instrument. Since the film-type instrument has only now been made available, all the field work has been done using the moving electrode, plate-type of klydonograph. With the electrode speed of this instrument, the time of a record could not be distinguished to a greater accuracy than 15 min. No practical attachment could be made with this type of instrument to speed up the electrode. Besides, this would have required changing of plates more frequently than once a day which would have unduly increased the expense of material and labor. When an operation is performed on a line requiring several switches to be thrown at various points, these are often thrown at intervals of a minute or so. Where a figure was recorded at the time of such a performance it was impossible to assign any particular operation as the cause. In order to obtain more concrete information as to the causes of surges, arrangements were made to have switches thrown at 15 min. intervals, when an operation was required, for certain periods during tests. During such periods much more satisfactory information was obtained as to the causes and actions of the surges recorded.

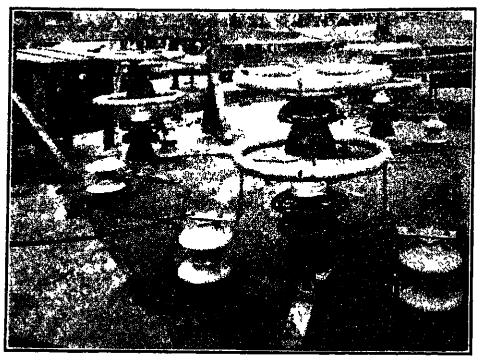

Fig. 30—30-Kv. Electrostatic Potentiometer

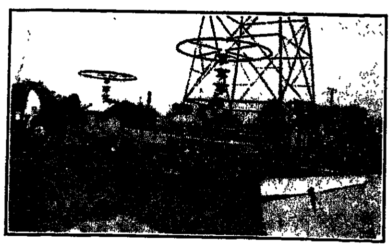

Fig. 31—140-Kv. Electrostatic Potentiometer

Potentiometers. Fig. 30 shows the potentiometer rings which were used on the 26,400-volt system. It was found that a 30-in. ring of 2-in. iron pipe, mounted as shown, was satisfactory on this class of voltage. The high potential element was mounted about 30 in. above the ground plate. The lower ring was placed at such a height that it had a potential of 3-kv. crest with normal voltage on the upper ring. This proved to be about 15 in. above the ground plate. For the higher values of voltage, the high potential element was raised and the ratio of distances changed to fulfill both the insulation and calibration requirements. Thus, to keep the proportions reasonable and a more uniform field, the sizes of the rings were increased with the voltage. Six- to eight-feet rings were used on the higher voltage lines. Fig. 31 shows the set-up used on the 140-kv. line and Fig. 32 shows the set-up used on the 220-kv. line. The height of the upper ring was between 8 and 12 ft. from the ground plate and the lower ring about 15 in., as before, to give 3-kv. crest with normal voltage on the upper ring.

Fig. 32—220-Kv. Electrostatic Potentiometer

In order to make the position of the ground beneath the rings constant, the rings were mounted on a metallic sheet consisting of either sheet iron or close-woven mesh. This ground plate was made large enough to extend about a foot beyond the outside circumference of the rings and solidly grounded.

An alternate form of potentiometer, shown in Fig. 33, was found feasible on the 220-kv. test and was used at three of the stations. The station busses on this system consisted of 4-in. iron pipes mounted parallel to, and 12 ft. from, the ground. A 10-ft. length of 3-in. iron pipe was mounted on insulators parallel to the bus at the proper distance above the ground plate, which was a 10- by 9-ft. plate of sheet iron lying on the ground and tied solidly to the station ground. This form of potentiometer has certain disadvantages which will be pointed out later.

The potentiometers were calibrated by measuring the

voltage on the lower ring with a 3/8-in. sphere-gap with normal voltage on the upper ring. When no series-gap is used, this calibration can be roughly checked by the width of the normal voltage line on the plate. With the potentiometer set to give 3-kv. crest with normal line voltage, the upper limit of the instrument, or 18-kv. crest, permits the measurement of a surge of six times normal voltage and the recording of a surge eight times normal before the instrument will spark over.

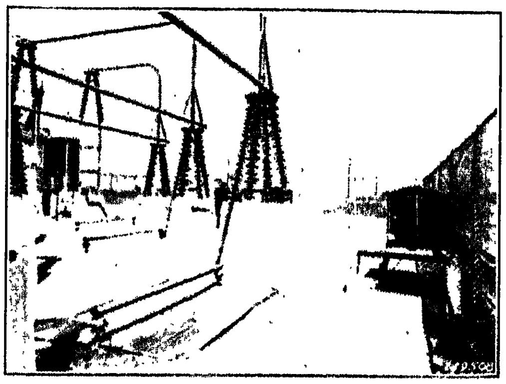

FIG. 33—220-KV. BUS TYPE POTENTIOMETER

At first some difficulty was experienced as a result of calibrating the potentiometers with the series-gap open. It was found that when a surge just high enough to break down the gap occurred, the figure on the plate indicated a somewhat lower voltage than the gap setting. The instrument itself had approximately 25 by 10^{-12}-farads capacity. By voltage tests with and without a series-gap the capacity of the lower potentiometer element to ground, in the case of the bus type, was about 125 by 10^{-12}-farads. Thus, there was a reduction of voltage on the klydonograph bus of about

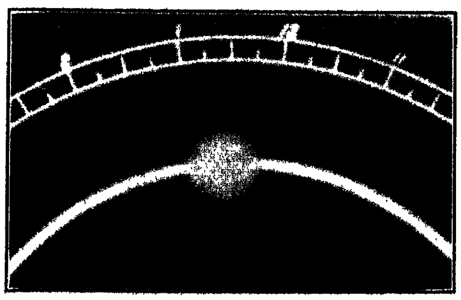

FIG. 34—SECTION OF PLATE WITHOUT SERIES GAP. OSCILLATORY SURGE

20 per cent upon breakdown of the gap. This error was eliminated by doing all calibration of the potentiometer with the instrument in place and the series-gap closed. It was also found that due to the capacities of the various elements in series it took a voltage 15 per cent above the setting of the gap to spark it over. This merely altered the lower limit at which the instrument began to record and could be taken care of by changing the gap setting. On two of the tests the series-gap was used and on the other two it was not. When no gap is used the smaller negative records are obscured by the band of normal positive figures. However, these are not important since a negative surge large enough to cause concern would show itself above this band. To operate without a series-gap gives a continuous check on the calibration of the potentiometers, a check on wide variations of the line voltage, and indicates a static potential on the line where this occurs. Fig. 34 is a section of a plate taken with the klydonograph operating without a series-gap. The surge shown indicates an oscillating surge. Fig. 35 is a section of a plate where a series-gap was used. The surge shown indicates a positive surge.

It was found that on a polyphase set-up the potentiometers must be set at some distances apart to prevent mutual effects between them. This presents no particular difficulty when rings are used as these can generally be placed at intervals along the line. In the case of the bus-type potentiometer, the separation of the station busses being fixed, this effect cannot be avoided. This makes the latter type a less accurate

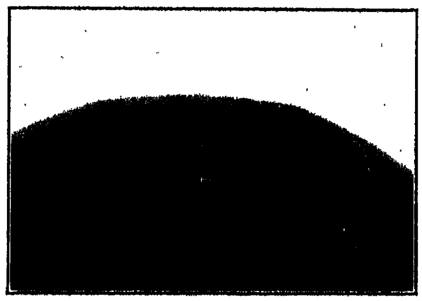

FIG. 35—SECTION OF PLATE WITH SERIES GAP. POSITIVE SURGE

set-up. It was found that in a particular case, where the height above ground was 12 ft. and the separation was 12 ft., one bus would affect the pipe of an adjacent bus to an extent of about 30 per cent. It was assumed in general that, except in the case of a lightning surge, a surge was unlikely to occur on two phases simultaneously and that, therefore, the calibration was correct when made with the adjacent busses dead.

In situations where the potentiometers were out in the weather, it was found to be imperative for all metallic parts to be painted. When this was neglected, the rust, running down on the supporting insulators, would create leakage and drop the potential on the lower ring to very low values.

Antenna. It was found that where the transmission line had a ground wire, this was generally in sufficiently close proximity to the line to act as an antenna. By insulating the wire on one tower, extending it down and grounding it through a suitable resistance, the antenna loop was complete. This could be made as long as desired by insulating the wire from as many

towers adjacent to the end tower as necessary. Fig. 36 shows an antenna set-up effected in this way. On lines where no ground wire was used, it was a simple matter to mount a wire on the transmission line poles or towers.

The antenna loop had a definite mutual inductance with each conductor and could be calculated with fair accuracy. At a fixed separation this can be varied by changing the length of the loop. At a given value of mutual inductance, the range of the klydonograph permits only a given range of steepness of wave fronts to be recorded. Such a value of mutual inductance was chosen that the steepest of the wave fronts encountered would not cause a flashover of the plate. A surge with a front too tapered to come within the range of the klydonograph with such a set-up was probably not abrupt enough to be serious.

The value of the mutual inductance with the various conductors was found to vary about 25 per cent in practical cases due to their different positions. In the case of an antenna record with a simultaneous potentiometer record on a particular phase, the mutual inductance with that phase was used in calculating dV/dt. In the case of a record caused by a steep-front surge, too small in magnitude to be recorded by the potentiometers, an average value of mutual inductance was used. In the case of simultaneous waves on the three conductors, the effects add algebraically. It was assumed that, in general, surges on three conductors caused by a switching operation would not be simultaneous when considering the propagation speed of electric waves. When the evidence indicated a lightning surge, the sum of the three mutual inductances was used.

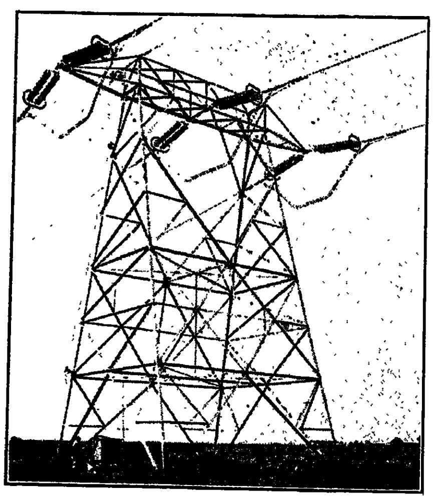

FIG. 36—ANTENNA CONNECTION ON 220-KV. LINE

Tests and Results. While up to the present writing there has not been time for as much field experience as could be desired, rather extensive tests have been made on four systems representing a wide range of conditions of electric power transmission.

a. These tests were made on a 26,400-volt system consisting of connected cable and open wire. Grounding was varied between solid and 150-ohm resistance. One instrument was installed on one phase at a substation having cables extending in each direction and another instrument on the same phase on the open-wire line, 18 miles from the junction of cable to open-wire. The tests were continued 20 days.

During this 20-day investigation 18 surges were recorded. The largest number in one day was three. All were obtained on the instrument on the open-wire line. A possible reason for this was the fact that the potentiometer was not painted for the greater part of the tests on the instrument recording no surges, with the resultant lowering of the calibration. Of these surges, seven were alternating, seven were positive, and four negative. As to magnitude of voltage, two were twice normal, six were 1.5 times normal, and ten were 1.3 times normal or less. As to weather conditions, eight occurred in clear weather, seven during rain, two in cloudy weather, and one during an electric storm. Both surges twice normal came during rain and wind. As to attendant causes, the two surges twice normal were not caused by a switch operation but switches were tripped by the disturbances. The one surge during an electric storm was 1.3 times normal. Of the total, nine were caused by switching and one by lightning. No cause could be assigned to the remainder, of which three came in clear weather and five during rain.

b. These tests were made on a 27,400-volt cable system. Only one instrument was installed at a pot head of a station with cables extending in both directions. The system was solidly grounded at one point approximately 10 mi. from the klydonograph. The duration of the test was 104 days.

During this investigation, 24 surges were recorded. One was 1.5 times normal, one was 1.4 times normal, and 22 were 1.3 times normal or less. Nine occurred in rain and 15 on clear days. The probable cause of the surge 1.5 times normal was a switch operation within three miles of the instrument. The 1.4 times normal surge occurred during switching operations.

c. These tests were made on a 240-mile, 140-kv. open-wire line with a free neutral. Three instruments each on potentiometers were installed at the receiving end, 65.5 mi. and 193 mi. from the receiving end and at the sending end. One antenna instrument was installed at the receiving end. The duration of these tests was 65 continuous days.

During this investigation, 124 surges were recorded on the potentiometer instruments. Of these, 22 were at the sending end, eight at the second station, 27 at the third station, and 67 at the receiving end. Fifty-four of these were 1.4 times normal or above and were distributed according to Table No. I.

TABLE NO. I

Surge Magnitude times normal	Sending end	Second Station	Third Station	Receiving end
3.5 to 4.2				2
2.5 to 3.5	1		2	6
2.0 to 2.5	5	3	1	7
1.4 to 2.0	5	3	4	15

In only two cases were surges recorded at more than one station simultaneously. In both of these cases, the surge was oscillatory and the maximum values of the surges were 4.2 and 2.8 times normal, respectively. Of these 54 separate figures, 15 were alternating caused by three surges; that is, some surges occurred on more than one phase and extended to more than one station; 21 were positive, caused by 13 surges, and 18 were negative caused by 18 surges.

Lightning caused nine a-c. figures in two surges, maximum values 3.3 and 2.8 times normal. Only one of these caused figures at more than one station. Lightning caused nine positive figures, all at the receiving end, in four surges, with maximum values of 4.2, 2.5, 1.5 and 1.3 times normal. No negative figures were caused by lightning. The other surge that was recorded at more than one station, causing seven figures in all, was caused by a telephone wire falling into and grounding one phase at about the middle of the line. The maximum value of the surge was 4.2 times normal at the receiving end.

Of the 54 figures, 1.4 times normal or above, switching caused nine. None of these were over two times normal. To about 80 per cent of the 70 figures below 1.4 times normal, no cause could be assigned. The others occurred at times of switch operations.

Except for a few mild lightning storms, the weather was in general fair.

The steepnesses of a total of 106 surges were recorded on the antenna instrument at the receiving end. Of these, 16 were simultaneous with records of magnitude on the potentiometer instruments. The maximum was due to one of the oscillating surges caused by lightning and was 28 by 10^6-kv. per sec. or indicated a frequency of 16,000 cycles. The next largest was due to an arcing ground and indicated 24 by 10^6-kv. per sec. or 9000 cycles. The steepest front surge caused by switching had a slope of 14 by 10^6-kv. per sec. and was unidirectional. Of the six lightning surges on the potentiometer, there were four to which there were corresponding antenna records. Of the 90 antenna figures with no simultaneous figures on the potentiometers, 20 could be connected with switching operations. There was no apparent cause for the remainder.

The varying relationship between the widths of the positive and negative portions of the normal voltage band indicated that this system would pick up and maintain for several hours a static potential of one or the other polarity.

This investigation has not been completed.

d. These tests were made on a 270-mi., 220-kv., open-wire line with neutral solidly grounded at four points along its length. Klydonographs were installed as follows: three on potentiometers at the sending end, three on potentiometers and one on an antenna at stations 105 mi. from the sending end, 140 mi. from the sending end; and at the receiving end. Tests were made on 120 days, covering 4½ months.

The results of this investigation are being discussed in a contemporary paper by R. J. C. Wood, of the Southern California Edison Company. They will therefore not be discussed in detail here. There was an unusual amount of system switching performed during the investigation and a resulting large number of surges were recorded. However, none of these were of alarming magnitude. The maximum surge recorded was 3.2 times normal voltage to ground. The next highest was 2.7 times normal. During the tests, there were two flashovers of line insulators, neither of which caused a higher voltage than 1.9 times normal, and this might have been caused by a switch operation within a few minutes of the flashover. The weather was fair during the investigation with no lightning.

Oscillations. There have been certain theories advanced regarding the existence of high-voltage, high-frequency oscillations on transmission systems. The above tests while not broad enough to be conclusive on all systems have indicated nothing to substantiate these theories except in the case of an arcing ground. Further, arcing grounds on a grounded-neutral high-tension line produced no high voltage oscillations, and in the case of the free neutral system, the frequency of oscillation did not exceed 16,000 cycles.

IV. Commercial Type of Roll-Film Recorder

A roll-film type of single-electrode klydonograph was under consideration before the construction of the glass-plate type. However, in order to cause as little delay as possible in obtaining a few field instruments, the rotating-electrode plate-type was chosen because of the certainty of its operation with standard clock and standard dry plates.

As soon as the plate-type of recorder proved that the klydonograph was very valuable in obtaining data on surges on transmission systems, the complete design and construction of the roll-film type was undertaken.

Some of the desirable features to be incorporated in such a recorder are as follows:

1. Daylight loading and unloading
2. Independent of power for operation, hence clock-driven
3. At least three electrodes desired
4. A long record possible, hence roll film to be used
5. Time markings correct without resorting to cog-wheel drive and holes in edges of film
6. Capable of standing considerable over-voltage
7. Reasonably constant in its calibration
8. Simple and reliable in operation

9. Truly portable; reasonably small and light
10. Rugged and not too expensive in construction

In order to harmonize these desirable features, a design radically different from that of any existing graphic instrument is required for this klydonograph. In such instruments. the torque required to reroll the chart is constantly increasing from beginning to end, and hence must be supplied by a separate clock spring or motor. The same type of reroll was chosen for this klydonograph as was designed for the long-film attachment for the three-element portable oscillograph. This incorporated the daylight-loading feature and constant torque for driving film and reroll.

Daylight Loading Film. A 6½-in. width of roll-film was chosen as a desirable width for a good three-electrode chart. This film was obtained on a metal, flanged spool having extra deep holes in the ends to permit the introduction of steel pins to act as shafts. These special films are put up in cartons marked for the klydonograph. A film length of 8 ft. was chosen to give a one-week record with a film velocity of ½-in. per hr. Fig. 37 shows this film in place in the klydonograph. The system consists of a main clock-driven drum over which the film passes on its way under the electrodes. The outer shell of the drum is micarta insulation. Beneath this is a thin metal sheet moulded into the micarta tubing. The metal sheet is grounded, through the metal ends of the drum, to the frame. It is practically impossible to make a thin film lay flat on a glass plate and touch all parts of the surface. However, it is much easier to make a film roll over a micarta cylinder and hug the cylinder so as to have no air spaces between the film and the cylinder under the electrodes of the klydonograph. In this design, we have a repetition of the essential features of the original klydonograph. The film used in this klydonograph has black paper on each end but none under the film itself. This permits of daylight-loading and daylight-unloading without introducing an undesirable member between the film and the internally grounded drum.

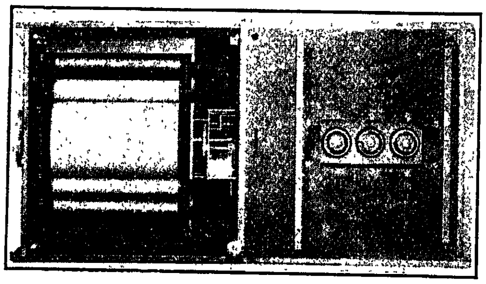

FIG. 37—THE KLYDONOGRAPH, COVER REMOVED, SHOWING FILM IN PLACE

Reroll Scheme. The general construction of the rerolling system can be seen in Fig. 37. On one side of the main drum is the unexposed film; on the other side is the exposed film. Beyond each of these is a roller with pulleys attached. Two helical-spring belts hold the rollers against the film cartridges, and, in turn, the cartridges against the main drum. If the under side of each belt is tight and the upper side relatively slack, the film will be drawn tight over the top half of the main drum. Now, as the main drum is turned by hand, or by the clock, the unrolling action from one spool will cause a rolling-up action on the other spool by means of the rollers and the two belts. The driving pulleys are made larger than the driven pulleys so that the under side of each belt will remain tight and the upper side relatively slack. Thus the film is urged to roll up faster than it is unrolled from the first spool. The rollers and film spools are held in alinement by shaft extension, free to slide in longitudinal grooves in the metal frame.

No slipping of either film or rollers takes place, for the ratio of the pulley diameters is so chosen as to keep the twisting torque as high as possible and yet well below the point where the rollers would slip on the film. In other words, the sum of the four tensions in the belts, multiplied by the coefficient of friction between the film and the rollers, is always greater than the sum of the differences between the tensions in the tight sides and the slack sides. The belts have no tendency to continue to accumulate tension on one side. If each driving pulley is a certain per cent larger in diameter than the driven pulley, then the slack side of the belt will have that same percentage greater number of turns than the tight side. The belt stretches as it leaves the driven pulley and contracts again as it leaves the driver pulley, and so on, indefinitely. Thus, there is no slipping of any member and no tendency to break the helical-spring belt.

It is easily seen that the peripheral speed of the main-drum surface, the film surface, the driving-roller surface, and the driven-roller surface is the same. Also the torque required to drive the drum, and thence the reroll, etc., is constant. As the unexposed film-roll decreases in diameter, the exposed roll increases in diameter, and the film shafts and the roller shafts shift along in the horizontal groove. The center distance between the pulleys remains practically constant with this arrangement and hence the tension in the belts does not change. All of these novel features go to make a simple but reliable reroll system which may be driven by a single clock.

Time Marker. Since the photographic chart is friction driven, it is necessary to devise a time-marking system which will show no error, due to any slight creepage of the film as it passes on its way over the main drum. The clock is geared to the drum so as to drive the film at a uniform speed of approximately one foot per day. The drum actually makes just one revolution in 24 hours, yet the film-travel, in seven days, may vary as much as an inch. If the time markings had a

3. JOURNAL of the A. I. E. E., Vol. XLII, p. 109—Legg: Portable Oscillograph.

proportionate error this would represent two hours. By means of a stationary speck of *luminous paint,* just under one edge of the drum cylinder, and twenty-four equally distributed holes through the outer edge of the cylinder, a dot is exposed on the edge of the photographic film every hour, and a dash every sixth hour. Each hole passes over the speck of luminous paint just as that hole lines up with the three electrodes. Hence, there can be no error in time marking, even if the film should vary several inches in its travel during one week, provided the 8-day clock keeps good time.

An *Hour Circle* is provided on the end of the main-drum shaft on the outside of the klydonograph. This has 24 graduations, each of which lines up with an index at the same time as the corresponding hole in the edge of the cylinder lines up with the electrodes. If the clock loses or gains a few minutes during the week, this can be checked by the reading on the hour circle and later allowed for in estimating the true time of occurrence of surges which may appear on the developed film.

The four dashes, per 24 hours, are all alike so that any one of them may be 6 o'clock or 12 o'clock, day or

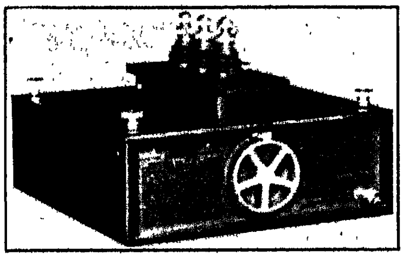

FIG. 38—FILM-TYPE KLYDONOGRAPH—GENERAL VIEW

night. This is done to save film when initially setting the instrument. *A daylight intensity* record appears on the opposite edge of the film from the dots and dashes. Daylight enters the case through a horizontal hole in the upper part of the klydonograph and is reflected downward through a vertical hole in the cover to a point on the film in line with the electrodes, thus giving the record of day and night, by reference to which it is easy to determine which time-dash is 6 a. m., which 12 m., which 6 p. m., and which midnight. A 45 deg. whitened surface, on the inside end of a screw, at the conjunction of the horizontal and vertical light holes, may be twisted so as to regulate the amount of light reaching the edge of the film. At any setting, daytime can be told from night, but by adjusting the amount of reflection according to the locality and position of the klydonograph, it is possible to get a record of the variation in intensity of daylight as caused by changing cloud conditions. This last feature is not essential but is often very helpful in checking up the causes of surges which appear on the film.

Complete Instrument. The complete roll-film type of klydonograph is shown in Fig. 38. The parts which appear on the outside are: the three electrode-terminals; their lead-in bushings; the daylight-intensity adjustor, on one side of the electrode chamber; the cover thumb-nuts; the hour circle, on the instruction panel; and the ground-binding-post. The outfit is but 12 by 12 by $8\frac{3}{8}$ in. over all, the case proper being but half that height. This three-electrode seven-day

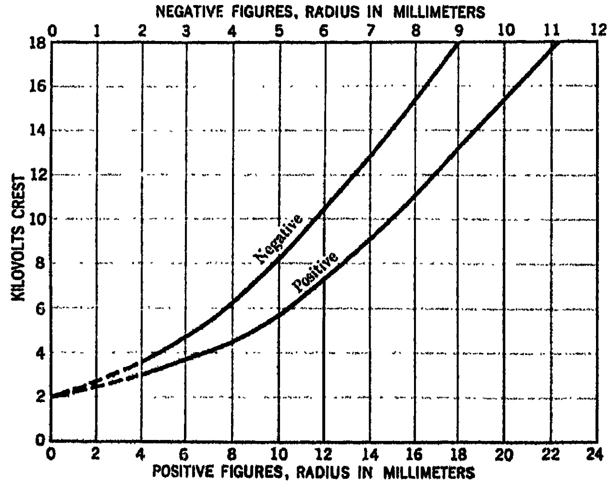

FIG. 39—CALIBRATION OF KLYDONOGRAPH—FILM-TYPE, EXPERIMENTAL MODEL

recorder is no larger than the original single-electrode 24-hour plate-model. Its weight is much less than many single-element graphic meters. It is so portable that it may be taken to any desired location on a transmission system, and in fact, in some cases located up in a transmission tower. For accurate work, special electro-static potentiometers, previously described in

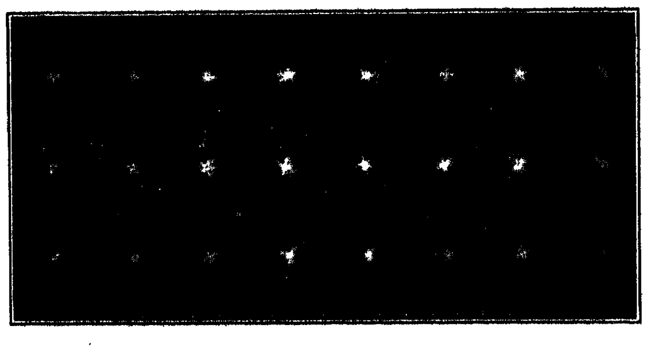

FIG. 40—SECTION OF TYPICAL FILM. ARTIFICIAL SURGES PRODUCED IN LABORATORY

this article, must be used. However, some information can often be obtained by tapping in between the first and second insulators, when of the multiple unit type, so as to lead a fraction of the voltage of each of the lines, of a three-phase system, to an electrode of the klydonograph.

Condensed instructions for loading and operating the instrument are moulded into the micarta panel each

side of the hour-circle. The hour-circle and the ground binding-post are in a recess, so that there is no protrusion beyond the 12 by 12 cases. The top of the movable part of each electrode is protected by a cap-nut over the electrode binding-post. With this arrangement, no delicate mechanism of any kind is exposed, and the instrument may be carried or shipped without danger of breakage.

Introduction and Removal of Film. In loading the klydonograph the whole top is removed, with the electrodes attached. The 8-ft. roll-film, with steel pins in spool ends, is inserted between the main drum and the roller having the larger pulleys. The opaque-paper end is brought up over the main drum and inserted in the slot in the empty spool between the other roller and the drum. This spool is turned until the opaque paper is tight over the upper half of the drum and the second roller is twisted until the lower halves of both spring belts are tight and the upper halves relatively slack. The cover is then replaced, with the electrodes bearing on the opaque paper on top of the drum. The hour circle is then drawn out, thus disengaging the drum from the clock pinion, and is turned until the joint between the opaque paper and the sensitized film is detected by the upward movement of the electrodes (easily seen, or felt, when the cap-nuts are removed). The hour circle is turned in until the graduations indicate the proper hour and fraction thereof, taking the nearest long mark to represent the nearest quarter of the day (6 or 12 o'clock, day or night). At this proper setting the hour circle is released so that the gear on the other end of the drum shaft engages with the clock pinion, thus driving the film ½ in. per hr., for seven days. Meanwhile the daylight-intensity indications, the luminous-paint time markings, and any surge phenomena have made their impressions on the photographic film. After the seven days are up, the hour circle is pulled out and turned onward so as to roll up the last of the film and opaque paper on the second spool. The cover is then lifted and this rerolled film-cartridge removed, without resort to a dark room. Later the films may be developed by any photographer or by the operator in a suitable dark room.

Calibration and Tests. The calibration of this roll-film-type of klydonograph proved to be very nearly the same as that for the plate type, the main difference occurring at the lowest perceptible voltages where the effect of the dielectric constant, and thickness, is most apparent. Fig. 39 shows the calibration chart of radius of figures (both positive and negative) to crest volts applied. Fig. 40 shows a short length of film with artificial surges, timing dots and dashes, and daylight-intensity record. The surge figures are described in detail in earlier parts of this article. Although the normal continuous potential on the electrodes of this instrument will be adjusted at 2500 volts, approximately, tests were made with a-c. potentials as high as 25,000 volts without damaging the instrument or puncturing the film. The calibration is not satisfactory beyond 18,000 volts, but this is 700 per cent above normal, and hence gives a very great range to the instrument. Since there is no power backing the surges as picked off an electrostatic potentiometer, and since the instrument stood higher voltages, backed with power, than can be met in practise, it is undoubtedly safe for the service intended.

Discussion

D. W. Roper: One of the first things that is necessary in order to make improvements in power cables is to know what causes the failure. A paper on dielectric losses in relation to cable failures[1] presented before the Niagara Convention outlined one cause of failure and the method of determining when such failures occur. A study of the failures on the cable system in Chicago, however, indicated that only 40 per cent of the failures of the transmission cables could be accounted for on this basis, and we had to look elsewhere for the balance.

Then it was noted that there were occasional simultaneous failures of switches in generating stations or substations and cables. There was a continuous discussion as to which was the cause and which the effect, and the cause was difficult to determine until the office cat wandered into the switch-house and came in contact with a line reactor. That gave us a very definite cause and when a cable failure occurred at the same time we knew the station trouble was the cause and the cable failure the effect.

That was verified later at another station where a rat got across the insulation of a switch connected to the generator bus and on that occasion two cable failures resulted.

The interesting part is that we know definitely that from these transient voltages cable failure is caused, and the next thing to do is to get some idea of the nature and voltage of these transients. For a number of years we have been securing records by means of needle gaps, but it was hard to tell just what they meant. When a transient sparks across a needle gap, you know that the voltage of the transient is greater than the voltage required to spark across a needle gap, but you don't know how much greater; it may be 10 per cent greater or 100 per cent greater. But in the klydonograph we get an instrument which will tell us that particular quantity.

In the Dufour oscillograph we get an instrument which will give us more intimate information regarding the nature of these transients, their shape and their voltage. The interesting thing about these transients and their frequency is that the theoretical men tell us that high-frequency transients do not travel, and that they cannot travel on underground systems. Then we have a disturbance like this cat and the reactor performance at one place and the cable failure occurs a few miles away. They say that the transient must be due to the effect of the discharge of the magnetic energy in the transformer, but it sometimes occurs a mile or two away from a transformer, and in such a way that the only path from the switch that fails to the cable that fails is through two line reactors which are said to stamp out transient voltages of that frequency.

With the advent of these new tools, we may call them, for attacking the problem of the troubles which occur on our cables, we should be able very shortly, with the continued assistance of the companies in whose laboratories these tools have been developed, to determine first the cause of the failures of our cables and afterwards the cure.

K. B. McEachron: We have been making a few preliminary tests, using the klydonograph and we believe it will be a very useful tool. There is just one point that I wish to bring up

1. Dielectric Losses and Stresses in Relation to Cable Failures, by D. W. Roper, A. I. E. E. TRANSACTIONS, Vol. XLI, 1922, p 547

regarding the calibration for different wave fronts in connection with the work that we have done recently.

Near the beginning of the paper it is stated that a 25-cycle wave would produce a figure of the same size as a wave of short front. We have briefly investigated the effect of using single half cycles of a 60-cycle wave so as to separate the positive and negative figures. This was done by a special synchronous switch, recording the wave form by an oscillograph. To give only one case as an example, we found that a 60-cycle wave of 15 kv. maximum gave a negative figure with a radius of about 1 mm. while a steep-wave front impulse, about 0.01 microsecond, of the same voltage, gave about 10 mm. While there may have been reflections in the impulse circuit tending to increase the voltage, we could hardly expect more than two or three times the voltage due to reflections so that it seems probable that the difference in wave front is responsible for at least a part of the change in the size of the figures.

Based on such data, I want to question the statement that the size of figure is independent of the wave front. We believe that the same size of figure may represent considerably different voltages if the wave fronts vary through a wide range.

B. E. Hagy (communicated after adjournment): It may be of interest to describe briefly the results of some recent tests on the system of The Philadelphia Electric Company in which two of the klydonograph instruments were used.

The tests were made on one line of a double-circuit, 66-kv., ungrounded, open-wire tie line between two generating stations which are about 14 mi. apart. Both lines on the transmission towers are insulated for 110 kv. and have overhead ground wires. The oil switch at the end of the line farthest away from the point where the actual switching was done remained open throughout the tests.

The purpose of the tests was to determine the transient disturbances set up on this line by normal switching operations on the system. Attempts to propagate surges on the line were made by charging electrolytic lightning arresters, by shifting load from line to line, by picking up and dropping an unloaded but fully energized line, and by changing the ratio of some tap-changing transformers at one end of the line, etc. This testing was carried on over a period of two days and several readings of value were obtained.

On one of the two days, a polyphase klydonograph instrument was located at each end of the line, the purpose being to measure the surge voltages at both the sending end and at the distant open end which were expected to be of different magnitude due to attenuation, damping, corona, or other effects. On the second day, both klydonograph instruments were located at the same end of the line but on opposite sides of the line choke coil for the purpose of determining the voltage difference caused by the inductance of the coil. There were considerable differences in simultaneous readings at the two ends of the line and across the choke coil.

The highest value of surge voltage reached during the two days of miscellaneous testing was 4.3 times normal or 240 kv. crest to ground while there were several readings of over three times normal. The reading of 4.3 times normal as well as the majority of the other high readings were recorded when the unloaded but energized line was disconnected from the source by opening the high-voltage line switch.

An interesting point of information indicating desirable operating procedure is noted in comparing the results of switching on the high- and low-voltage sides of the step-up transformers. These results show that while almost no surges are produced when the switching is done on the low-voltage side, surge voltages of more than four times normal are produced when the switching is done on the line side of the transformer.

The changing of transformer ratio under load, the shifting of load at an intermediate substation, the energizing of the line, and the charging of lightning arresters produced only nominal surges, which is somewhat surprising particularly with respect to the operation of charging the electrolytic lightning arresters which was expected to cause surges of fair magnitude. In some cases, the voltages built up by reflection at the distant end of the line as well as the voltage on the line side of the choke coil were simultaneously greater than the voltages on the same phase at the source end and sometimes less. Only a few of these surges were oscillatory in character and these were rapidly damped.

These tests are, of course, of different significance from those described in the paper where the usual application of the instrument was to have it connected more or less permanently to the system over a fairly long period to record normal system surges due to atmospheric conditions as well as switching, while the purpose in the tests described was to reproduce several normal switching operations in a short period and in good weather for the purpose of determining the probable magnitude of switching surges in ordinary operation. Even under the less severe conditions, it will be noted that the voltages recorded are relatively greater than any previously reported. It may be that on a good many systems routine switching operations will produce surges of surprisingly high value.

The latest film-type polyphase instruments were used in these tests and the results secured and the experience with them show the device is convenient to use and gives ample voltage records the meaning of which is easily interpreted.

J. H. Cox: Mr. McEachron raised two questions; one was calibration of the klydonograph when the figures begin to slide, and the other was the accuracy of calibration for various frequencies or steepness of wave fronts. As brought out in the paper, when the figures begin to slide they do not behave in a consistent manner and the voltage is approaching the limit of the instrument. However, when these slides do occur there are nearly always some rays that enanate directly from the center and the length of these conforms to the calibration curve.

In the development of the klydonograph little work was done using wave fronts beyond two limits of length, that is, shorter than five microseconds and longer than that given by a 25-cycle wave. Most of the work was confined between five and 200 microseconds. A great many records were taken with surges as abrupt as could be produced by ordinary means and our work leads us to believe that these conform to the calibration curve of the more tapered surges. They were not used in obtaining these curves for the reason that the voltages produced in such a circuit are indefinite. When a spark-gap is discharged into a simple circuit, as done by Mr. McEachron, you cannot say with any degree of certainty what the voltage is at any part of the circuit. It required a great amount of work to set up a circuit that did not give reflections and oscillations. Successive records taken without changing a set-up did not vary as much as 1 mm. Further, when a single surge was impressed on six terminals tied together, no variation could be measured.

The klydonograph was developed for the purpose of recording transients on transmission systems. It has been gratifying to find that the surges present on practical lines have a wave front between one and 200 microseconds. In this range at least the klydonograph is entirely satisfactory. It must be remembered that no greater accuracy than 15 per cent is possible in such an instrument. This is ample for practical use.

When the application is as slow as a 60-cycle or a 25-cycle wave the conductivity of the film surface has an influence. A slight conductivity in the case of a slow application will allow some charge to leak off the electrode and thus tend to lessen the intensity of the field at the emulsion surface which is necessary to produce a figure. We have found commercial films to vary somewhat in this respect, but not enough to cause concern when dealing with surges. The performance of the instrument at commercial frequencies is not particularly important since there are more convenient methods of measuring such potentials.

Over-Voltage on Transmission Systems Due to Dropping of Load

E. J. BURNHAM[1]
Associate, A. I. E. E.

Synopsis:—*When a waterwheel-driven generator, or a hydroelectric station, loses all or a large part of its load, the voltage rises more rapidly and to a greater extent than has been generally realized.*

The purpose of this paper is to show the manner in which the voltage will rise under different conditions, and a method of calculating the voltage rise of a waterwheel-driven generator when load is lost.

The results of a large number of tests are given showing the rise in voltage on an 8500-kv-a., 6600-volt waterwheel generator when load was tripped under several different conditions at three different places, namely, at the generator, on the high-voltage side of a transformer bank, and at a substation forty miles away.

As it is not considered good practise to subject a transmission system to high over-voltages, consideration is given to methods of checking the voltage rise by use of relays as soon as possible after load has been dropped.

MUCH has been written about instantaneous rises of voltage due to switching surges, and transients due to short circuits, but very little has been said regarding the rise of voltage due to dropping of load on an a-c. system.

Great interest has been shown in various sections of the country during the past year in the voltage obtained when a waterwheel-driven generator, or a hydroelectric station, loses all or a large part of its load, since voltages obtained in this manner are much higher and develop more rapidly than would ordinarily be expected.

When load is lost on an a-c. generator, or group of a-c. generators, the manner in which the voltage rises and the time interval taken for such a rise varies according to the following factors:

1. Voltage regulation and design of the generator.
2. Type and speed regulation of prime mover connected to generator.
3. Generator excitation obtained from direct-connected exciter, exciter motor-generator set, or d-c. bus.
4. Amount and power factor of load dropped.
5. Voltage regulators used or not used.
6. Place in circuit where load is tripped.
7. Connections including lines, transformers, etc., between generator and load.
8. Over-voltage or over-speed devices used or not used.

With the above points in mind, calculations were made to determine the maximum rise in voltage on ordinary waterwheel-driven generators when load was lost under different conditions. The results of these calculations are shown in Table I. Details regarding method of making calculations are given later.

In order to check the calculations and to obtain further information, a series of tests[2] were made, in which load was dropped in different ways and under many different conditions on an 8500-kv-a., three-phase, 60-cycle, 164-rev. per min., 6600-volt, 80-per cent power-factor waterwheel generator, connected to a large 60-cycle system, through an 18,000-kv-a. bank of transformers and a 40-mile, 66,000-volt transmission line.

TABLE NO. I
VOLTAGE RISE IN PER CENT OF NORMAL VOLTAGE

Type of Prime Mover	Over-Speed	With Voltage Regulator		Without Voltage Regulator	
		With direct-connected Exciter	Without direct-connected Exciter	With direct-connected Exciter	Without direct-connected Exciter
Water-turbine....	25–35%	50–80%	40–65%	90–100%	60–85%

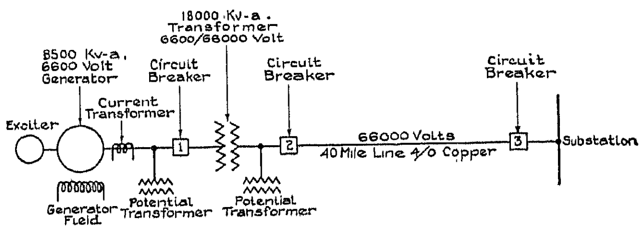

FIG. 1—ARRANGEMENT OF EQUIPMENT FOR TEST

Connections and arrangement of equipment between the generator and substation are shown by Fig. 1. By use of circuit breakers 1, 2, and 3, load could be tripped at any one of three different places. These circuit breakers will be referred to as generator, transformer-high-voltage, and substation circuit breakers, respectively.

The generator had a direct-connected exciter, but in order to also make tests with the generator separately excited, a temporary connection was made to a small, waterwheel-driven exciter. However, the limited capacity of this exciter would permit the generator when separately excited to carry only 4000-kw. load at 98 per cent power factor.

A vibrating type, 60-cycle voltage regulator was in the station, so plans were made to use that in some of the tests.

Connections were made to an oscillograph so that

1. Central Station Engineering Dept., General Electric Company, Schenectady, New York.

2. Tests were taken at the Spier Falls Station of the Adirondack Power & Light Corporation.

Presented at Regional Meeting of Dist. No. 1, Swampscott, Mass., May 7-9, 1925, and at the Annual Convention of the A. I. E. E., Saratoga Springs, N. Y., June 22-26, 1925.

TABLE II

Test	Oscillogram	Load dropped-kw.	Power Factor per cent	Direct-connected Exciter	Regulator	Over-voltage Relay	Over-Frequency Relay	Breaker tripped by Hand	Breaker tripped by Relay	Maximum Voltage in per cent of normal

15	97309	3500	66	Yes	No	Yes	No	2	1	138

any three of the following waves could be recorded at the same time:

1. 60-cycle or 40-cycle timing wave.
2. Generator field or exciter voltage.
3. Generator current.
4. Generator voltage.
5. High-tension voltage at a point between transformer and transformer high-voltage circuit breaker.

Table II gives details regarding tests in which load was dropped in different ways and under different conditions.

It will be noted that 6700 kw. was the largest load dropped. The generator could not carry a greater load than this because of the water conditions at the time the tests were made.

Commercial load was used for these tests; therefore, because of the system operating conditions, it was not always possible to drop the load most desirable for a particular test. However, by giving consideration to the amount of load dropped, proper comparisons may always be made between the different tests.

It will also be noted that after a load was dropped, in some cases the speed rise reached 152 per cent of normal, which is a much greater speed increase than generally obtained on waterwheels under similar conditions. This large speed increase is accounted for by the fact that the waterwheel governor had not received final adjustment, but this does not make the tests less valuable, since the speed characteristics for each test can be determined by making a comparison between the timing wave and the generator-voltage wave. Furthermore, the large speed regulation of the waterwheel was offset, to some extent, by the load dropped, which was less than normal; therefore, the results are not far from what might ordinarily be expected, as will be shown later.

Load Dropped by Tripping Generator Breaker Direct-Connected Exciter Used

Fig. 2 shows the results of two tests, a voltage regulator being used in Case 2, but not in Case 1. Curves 1 *A* and 2 *A* show the rise in speed that took place as soon as load was dropped. Curves 1 *B* and 2 *B* show the corresponding rise in generator voltage.

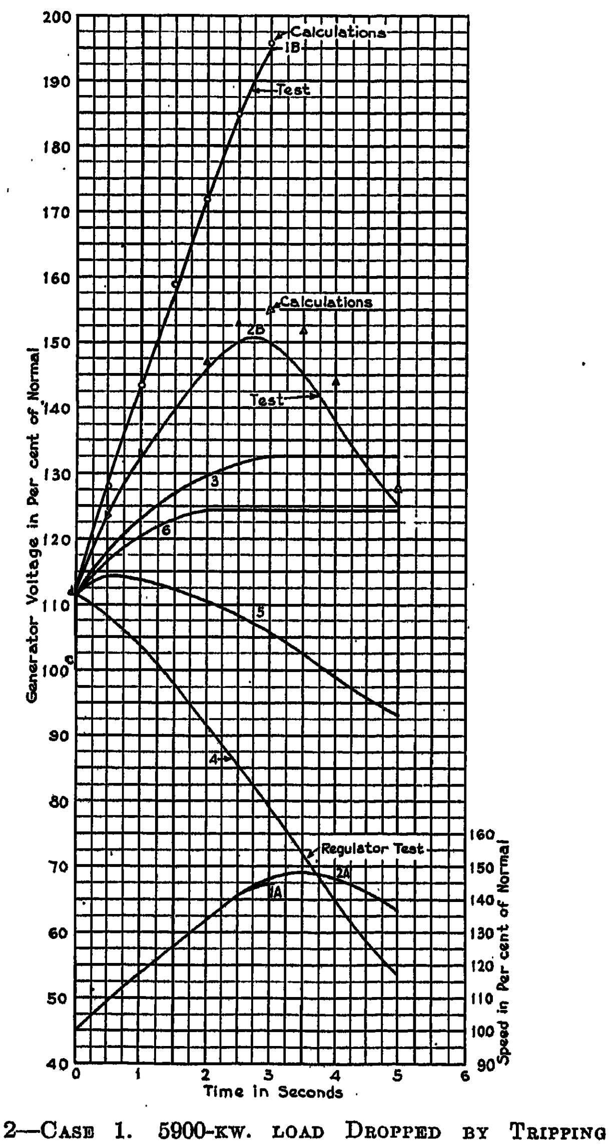

FIG. 2—CASE 1. 5900-KW. LOAD DROPPED BY TRIPPING GENERATOR BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR.

CASE 2. 6100-KW. LOAD DROPPED BY TRIPPING GENERATOR BREAKER. DIRECT-CONNECTED EXCITER. REGULATOR IN OPERATION.

The curves illustrate that as soon as the generator breaker was tripped, the generator voltage rose instantly to approximately 112 per cent of normal, and then increased in accordance with Curve 1 *B* or 2 *B*, 1 *B* being without voltage regulator and 2 *B* being with voltage regulator. The effectiveness of the voltage regulator is plainly seen when a comparison is made between Curves 1 *B* and 2 *B*. The maximum over-speed is greater in Case 2 than in Case 1, as shown by speed Curves 2 *A* and 1 *A*, due to the fact that a slightly larger amount of load was dropped in Case 2 than in Case 1.

Referring to Case 1, Fig. 2, the solid line 1 *B* represents test values as recorded on an oscillogram, while the small circles were plotted from calculations. In Case 2, solid line 2 *B* represents test values, while the small triangles are taken from calculations. The method by which the calculations were made will be given later.

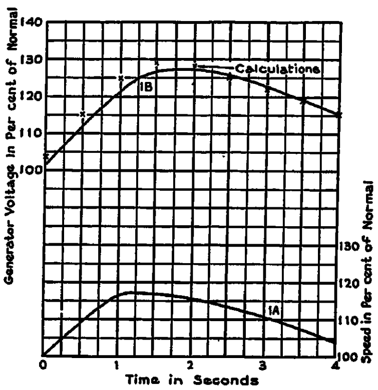

FIG. 3—4000-KW. LOAD DROPPED BY TRIPPING GENERATOR BREAKER. GENERATOR SEPARATELY EXCITED. NO REGULATOR.

LOAD DROPPED BY TRIPPING GENERATOR BREAKER GENERATOR SEPARATELY EXCITED

Results of a test in which the generator was separately excited are shown in Fig. 3. As only 4000-kw. load was dropped, the speed did not rise as high as it did in tests previously described.

After the load was dropped, the voltage increased in accordance with Curve 1 *B*. The small crosses represent points calculated.

LOAD DROPPED BY TRIPPING HIGH-VOLTAGE TRANSFORMER BREAKER DIRECT-CONNECTED EXCITER USED

Fig. 4 shows results of two tests, one taken with and one without voltage regulator. In each case, load was dropped by opening the high-voltage transformer breaker. Here, as before, the voltage regulator was very effective in limiting the rise of voltage.

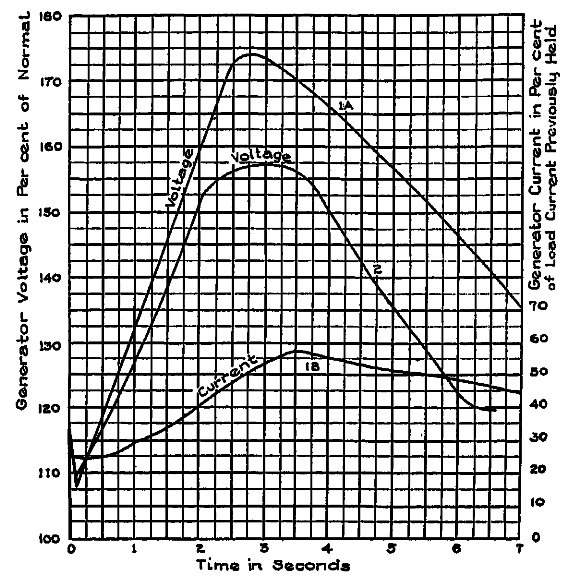

FIG. 4—CASE 1. 6500-KW. LOAD DROPPED BY TRIPPING TRANSFORMER HIGH-VOLTAGE BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR.

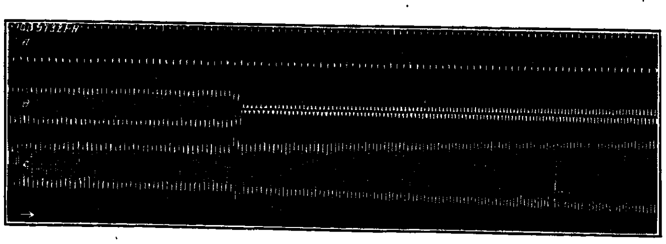
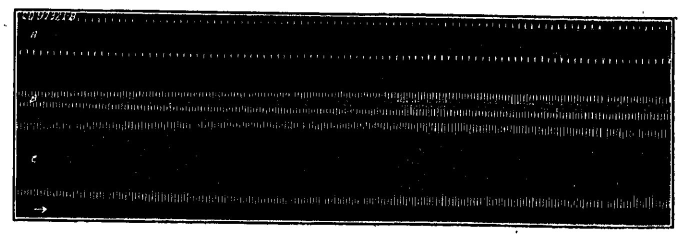
CASE 2. 6400-KW. LOAD DROPPED BY TRIPPING TRANSFORMER HIGH-VOLTAGE BREAKER. DIRECT-CONNECTED EXCITER. REGULATOR IN OPERATION.

Allowing for the different amounts of load dropped, it is seen that when the load was tripped by the transformer high-voltage circuit breaker, the voltage did not rise as high as when the load was tripped by the generator circuit breaker. This difference was due to the exciting current taken by the transformer after the high-voltage circuit breaker had been opened, which was load current for the generator. Curve 1 *B*, Fig. 4, shows how the transformer exciting current, or in other words, the generator-load current, increased as the voltage became greater and greater after load had been dropped.

Figs. 5A–B show part of the oscillogram from





FIGS. 5A-B—6500-KW. LOAD DROPPED BY TRIPPING TRANSFORMER HIGH-VOLTAGE BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR.

Curve *C*—Generator voltage

which Curves 1 A and 1 B, Fig. 4, were taken. The oscillogram shows how the transformer exciting current and the generator voltage increased in value after load was dropped, the middle wave being transformer exciting current and the lower wave generator voltage.

Fig. 6 shows part of an oscillogram similar to that of Fig. 5A, with the exception that a slightly different load was dropped. The middle wave indicates exciter voltage instead of generator current. This middle wave gives a good indication of how the exciter voltage increased in value as the speed increased, after the load was dropped.

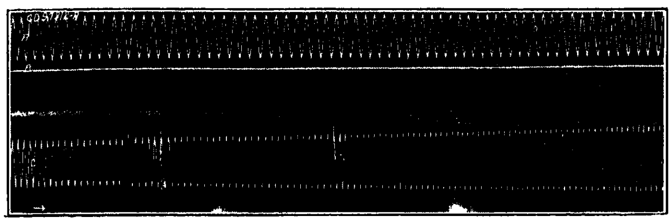

FIG. 6—6400-KW. LOAD DROPPED BY TRIPPING TRANSFORMER HIGH-VOLTAGE BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR.

Curve A—40-cycle timing wave

Curve C—Generator voltage

LOAD DROPPED BY TRIPPING SUBSTATION BREAKER DIRECT-CONNECTED EXCITER USED

Fig. 7 shows the results of two tests, one taken with, and one taken without, voltage regulator, in which load was dropped by opening substation circuit breaker. The voltage regulator was again very effective in limiting the voltage rise.

Curve 1 of Fig. 7 shows a 118 per cent voltage rise, which is a greater rise than obtained in any of the tests. This is only natural when consideration is given to the fact that the charging current of the 40-mile line more than offset the exciting current of the transformer, the effect of which was to boost the excitation of the generator.

Curve 2 B, Fig. 7, shows the generator current which is a resultant of transformer exciting current and line-charging current. In this instance, the current curve has two peak values, the dip in the middle occurring at the time the voltage reached maximum.

Figs. 8A–B show parts of the oscillogram from which Curves 2A and 2B of Fig. 7 were taken. The middle wave of the oscillogram shows clearly the dip in the generator currents mentioned above, and also the many harmonics in the current wave. The lower wave of the oscillogram represents the generator voltage and shows the switching surge at the time the high-voltage transformer circuit breaker was tripped, and just how the voltage increased after the load was tripped.

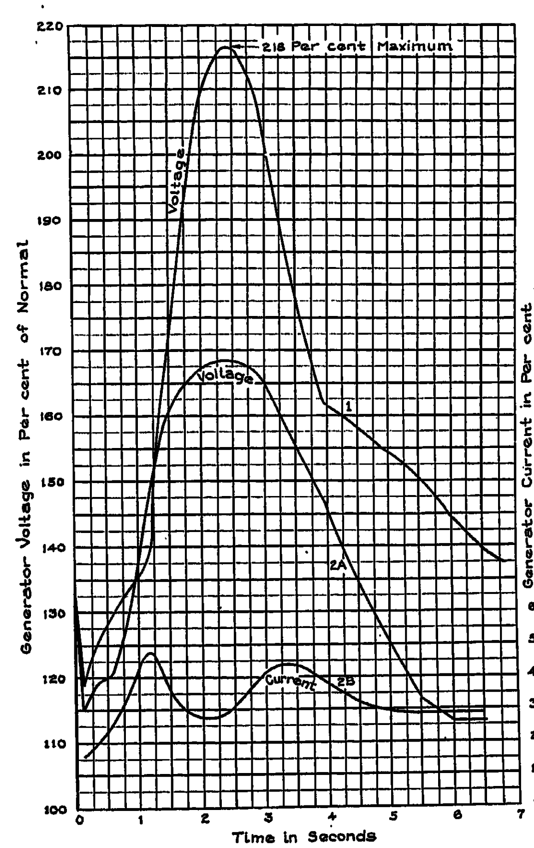

FIG. 7—CASE 1. 6700-KW. LOAD DROPPED BY TRIPPING SUBSTATION BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR.

Voltage Reduction

The tests already described show the rapid and extensive rise of voltage that occurs when load is lost on a waterwheel-driven generator. Believing it desirable to check the voltage rise as soon as possible after load is

TABLE NO. III
REDUCTION IN GENERATOR OPEN-CIRCUIT VOLTAGE

Test	Oscillo-gram	Previous Voltage in % of Normal	Method of Reducing Voltage	Time in Seconds for Voltage to decrease 50%
16	97302	143	Insert Resistance in Exciter Field Circuit	4.75

Case *b*: by Opening Exciter Field Switch.
Case *c*: by Tripping Generator Field Circuit Breaker.

dropped, a series of tests was made to determine the speed with which the generator open-circuit voltage could be reduced by three different methods. A tabulation covering these tests is given in Table III. Fig. 9 shows the results of three of these tests, each

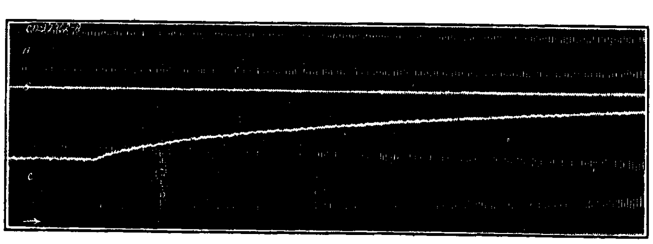

Fig. 10—Generator Open-Circuit Voltage Decreased by Inserting Resistance in Exciter Field Circuit

Curve *B*—Exciter voltage
Curve *C*—Generator voltage

method being represented. Curve *a* shows the rate of voltage decrease when a block of resistance was placed in the exciter field circuit, this being accomplished by holding the voltage regulator contacts open. Curve *b* shows the rate of voltage decrease when the exciter field switch was opened, and Curve *c* the rate of voltage decrease when the generator field circuit breaker was tripped. Field discharge resistors were, of course, used in the last two cases.

Fig. 9 shows the advantage of tripping the generator

shows the way the exciter voltage decreased when a block of resistance was placed in the exciter field circuit.

Fig. 11 shows the oscillogram from which Curve *c* of Fig. 9 was taken, the generator field circuit breaker

being tripped at a time when the generator was operating at normal voltage, no load. The middle wave of oscillogram shows how the generator field voltage decreased after the field circuit breaker was opened. It will be noted that the generator field excitation was reversed in polarity at the time the field circuit breaker was tripped.

Fig. 12 shows the effect of tripping the generator field circuit breaker, as well as the generator main circuit breaker, after load had been dropped by opening high-voltage transformer circuit breaker by hand.

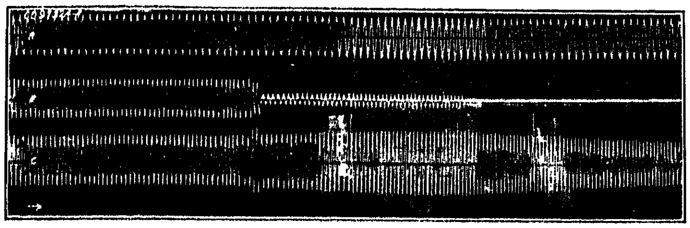

FIG. 13—6150-KW. LOAD DROPPED BY TRIPPING TRANSFORMER HIGH-VOLTAGE BREAKER. DIRECT-CONNECTED EXCITER. REGULATOR IN OPERATION. OVER-FREQUENCY RELAY TRIPPED GENERATOR BREAKER.

Curve *A*—40-cycle timing wave
Curve *B*—Generator current
Curve *C*—Generator voltage

Curves 1 *A* and 2 *A* show the rise in speed and Curves 1 *B* and 2 *B* show the corresponding voltage changes, when load was dropped. The difference in the two speed curves is due to the fact that more load was dropped in Case 1 than in Case 2.

Voltage Curves 1 *B* and 2 *B* are also different. In Case 1, the generator and field circuit breakers were tripped by an over-voltage relay set at 115.5 per cent of normal voltage. In Case 2, the generator and field circuit breakers were tripped by an over-frequency relay set at 63 cycles or 105 per cent of normal frequency. In each case, auxiliary contactors were used with the relays so arranged that the trip circuits of the generators and field circuit breakers would be energized at the same time.

OVER-VOLTAGE AND OVER-FREQUENCY RELAYS

The curves in Fig. 12 give information regarding the operation of the relays, as well as information regarding the voltage and speed changes. In Case 1, the generator and field circuit breakers were tripped sooner than in Case 2. This was due to the fact that the over-voltage relay in Case 1 was operated by the initial voltage impulse which reached approximately 130 per cent of normal, while the over-voltage relay in Case 2 did not operate until approximately a quarter of a second later when the speed reached 105 per cent of normal.

Fig. 13 shows part of the oscillogram from which Curves 2 *A* and 2 *B* of Fig. 12 were taken. The middle wave on the oscillogram represents the generator current and indicates clearly the time when the high-voltage transformer circuit breaker opened and also the time when the generator circuit breaker opened. By use of the 40-cycle timing wave, it is found that the generator circuit breaker opened approximately 0.73

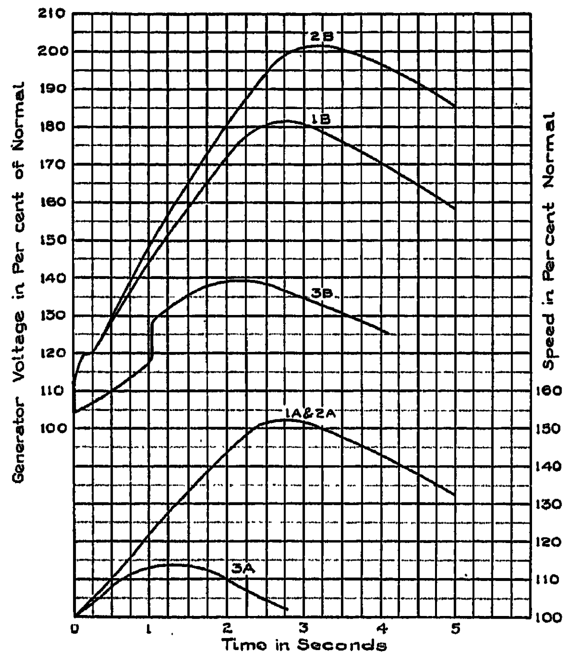

FIG. 14—CASE 1. 6700-KW. LOAD DROPPED BY TRIPPING SUBSTATION BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR. OVER-VOLTAGE RELAY TRIPPED TRANSFORMER HIGH-VOLTAGE BREAKER.

CASE 2. 6700-KW. LOAD DROPPED BY TRIPPING SUBSTATION BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR. OVER-VOLTAGE RELAY TRIPPED GENERATOR BREAKER.

seconds after the high-voltage transformer circuit breaker was tripped.

Three different tests are represented in Fig. 14. An over-voltage relay was used in Case 1 and Case 2, but

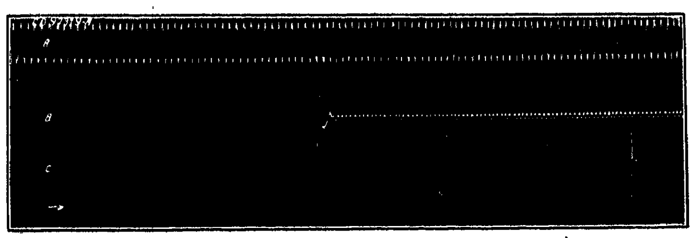

FIG. 15—6700-KW. LOAD DROPPED BY TRIPPING SUBSTATION BREAKER. DIRECT-CONNECTED EXCITER. NO REGULATOR. OVER-VOLTAGE RELAY TRIPPED GENERATOR BREAKER.

Curve *A*—40-cycle timing wave
Curve *B*—High-tension voltage at transformer terminals
Curve *C*—Generator voltage

in Case 3 a combination relay of both over-voltage and over-frequency was used. In the latter case, the over-voltage element was set at 115 per cent normal voltage, and the over-frequency element was set at 105 per cent

normal frequency. The contacts of both elements were placed in series, so the tripping circuit of the generator breaker would not be energized until each set of contacts had been closed. An analysis of the curves shows that the contacts of the over-voltage relay closed approximately 0.5 seconds later than the closing of the over-frequency relay contacts.

In Case 1, the relay tripped the high-voltage transformer circuit breaker, while in Case 2, the relay tripped the generator circuit breaker. In Case 1, the transformer exciting current furnished load for the generator; therefore, the voltage did not rise as high as it did in Case 2, where the generator had no load after the generator breaker was tripped.

Fig. 15 shows part of the oscillogram from which Curve 2 *B* of Fig. 14 is taken. The middle wave of the oscillogram represents the voltage on the high-voltage side of the transformer. The small voltage indicated after the generator breaker was opened was induced from a 110,000-volt, 60-cycle line, which parallelled the line being used for these tests.

Generator Circuit Breaker and Relay Tests

In order to check the operation of the relays, two tests were made with the use of the oscillograph, one to determine the operating time of the generator circuit breaker and the other to determine the operating time of the over-voltage relay. The results of the tests are shown in Table IV.

TABLE IV
OPERATING TIME
GENERATOR CIRCUIT BREAKER AND OVER-VOLTAGE RELAY

Test	Oscillogram	Equipment	Operating Time Seconds
20	97314	Generator Breaker and Relay	0.21
21	97315	Generator Breaker	0.11

General Considerations and Calculations

Voltage Regulation. Due to regulation, the voltage of an a-c. generator carrying full load at normal speed and voltage will generally rise between 25 and 35 per cent above normal when load is lost, providing the speed and excitation remain constant.

Part of this rise in voltage is instantaneous and part takes place over an interval of time. Consider the 8500-kv-a., 6600-volt a-c. generator used in the tests just described, and assume that it is carrying a load of 5900 kw., 0.83 per cent power factor, as in test No. 1.

When carrying this load, the calculated internal or generated voltage is equal to 111 per cent of the terminal voltage. The internal voltage differs from the terminal voltage by the amount of impedance drop in the stator winding. If the load just mentioned is dropped, the terminal voltage will instantly rise to a value equal to the internal voltage because the flux to produce this voltage is already present in the stator and because the impedance drop in the stator winding disappears as soon as load is dropped. Referring to Fig. 2, this instantaneous voltage rise is shown by line *c d*, the calculated value being 111 per cent and the test value being 112 per cent of normal voltage.

Using calculations and assuming, further, that the speed and excitation remain constant, the voltage will increase from 111 per cent voltage to the open-circuit voltage. This rise of voltage is shown by Curve 6, Fig. 2, and takes place over an interval of time, because after load is tripped and armature reaction disappears, time is consumed in building the stator flux up to a value corresponding to the field m. m. f.

For an average generator on which full load is lost, this time may be assumed to be two seconds, but varies to some extent, according to the size and design of the machine in question.

Prime Mover. As the governors of waterwheels and steam turbines are speed devices, a change in load is always accompanied by a change in speed. Given sufficient time, the new output of energy will be produced at a new steady speed. (Only by readjustment of the governor can the new output be produced at the previous speed.) When the decrease of load is great and sudden, the speed will rise higher than the ultimate speed, this over-shooting being due to the inability of the governor system to follow quickly enough the speed of the turbine rotor.

The overspeed of water turbines when full load is lost varies according to the horse power of the turbine, the time taken to close the guide vanes, the $W R^2$ of combined generator and turbine unit, the rev. per min., and the length of penstocks. However, these different factors combine in such a way that for an ordinary design of water turbine, the overspeed is usually between 25 and 35 per cent when load is dropped.

Fig. 16 shows some typical speed-time curves indicating the rise in speed on a large water turbine when different amounts of load were dropped. In this particular case, the speed rose to 131.5 per cent of normal, when full load was dropped.

In the tests referred to in the first part of this article, the speed regulation was greater than customary for the reason already given, namely, the waterwheel governor had not received final adjustment.

The maximum speed attained by a steam turbine when load is suddenly removed is much less than that attained by a water turbine under similar conditions.

Tests taken on a 30,000-kw. steam turbine show that when full load was dropped the governor action was such that the maximum speed attained was only four per cent above normal. This maximum speed was reached in one second. Upon dropping a 75 per cent load on the same turbine a maximum speed rise of 2.75 per cent normal was attained in 0.9 seconds. Even if the emergency governor of a steam turbine is called upon to operate, the speed will generally not rise above 110 per cent of normal.

In view of the foregoing, the danger from the over-

voltage on steam stations is not as great as on hydroelectric stations.

Generator Excitation. Field excitation for a-c. generators is generally obtained by one of the following methods:

1. D-c. bus.
2. Direct-connected exciter.
3. Exciter motor-generator set.

The maximum over-voltage obtained when load is dropped depends, to some extent, on which method of excitation is used, as a direct-connected exciter will overspeed with the generator when load is dropped. The same is true of an exciter motor-generator set if the motor of the set receives power from a circuit connected to the a-c. generator which loses load.

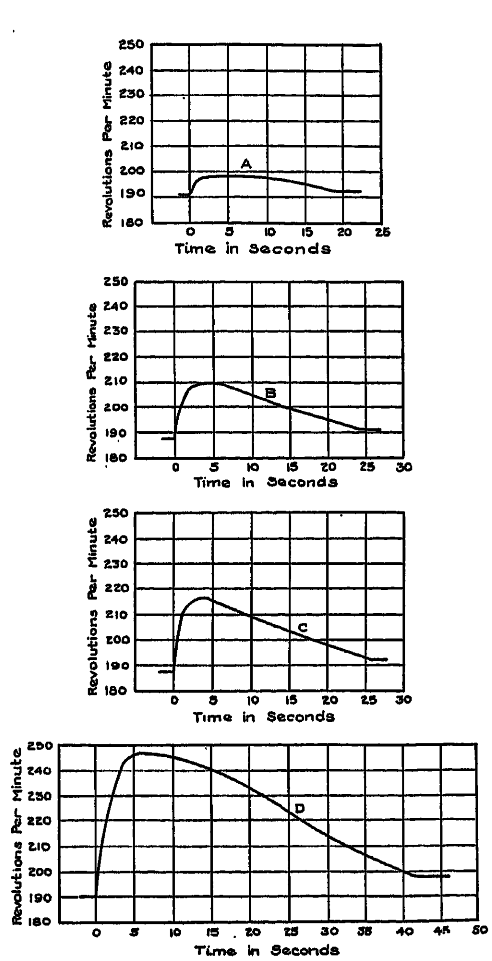

FIG. 16—LOAD REJECTION ON A 44,000-KW. WATER TURBINE
Case *A*— 39.8 per cent load dropped
Case *B*— 58.0 per cent load dropped
Case *C*— 67.0 per cent load dropped
Case *D*—100.0 per cent load dropped

An increase in the speed of the exciter causes an increase in the exciter voltage, which, in turn, causes an increase in the a-c. generator field current and, therefore, a further rise in the a-c. generator voltage.

For exciters generally used, the armature voltage increases approximately as the square of the speed, as the speed is increased above normal. The a-c. generator field current increases in direct proportion to the increase in exciter voltage providing the resistance in the field circuit remains the same, but the a-c. generator voltage will not increase in direct proportion to the increase in field current due to saturation of the iron in the generator magnetic circuit. However, if a waterwheel-driven generator, having a direct-connected exciter, drops load, the field current will rise to such an extent that the open-circuit voltage will usually reach the upper part of the saturation curve, which is nearly flat.

Referring again to Fig. 2, the voltage rise shown by Curve 6 assumes no increase in speed when load is dropped, and assumes the generator to be separately excited. If the speed is increased and field excitation held constant, the voltage will actually rise above this Curve 6 in direct proportion to the increase in speed. This is true because the open-circuit voltage of an a-c. generator is always proportional to the generator speed, providing the excitation remains constant.

Now assume that the 8500-kv-a. generator has a direct-connected exciter and that it is connected to a waterwheel having a speed characteristic as shown by Curve 1 *A*, Fig. 2. Curve 3, Fig. 2, shows how the generator voltage increases to 132.5 per cent of normal assuming an overspeed on the exciter, but no over-speed on the generator. (This is a physical impossibility, but is suggested as a step toward determining the actual voltage). Instantaneous increase in voltage *c d* is the same as before. For the voltage rise indicated by Curve 3, a time lag of three seconds has been assumed, which takes into consideration the lag of flux change in both the exciter and the a-c. generator.

When the load is dropped, the generator, as well as the exciter, overspeeds; therefore, the calculation of the actual generator voltage curve for this condition involves increasing the value of the voltage points on Curve 3, in accordance with the increase in speed, as shown on speed Curve 1 *A*. The resulting calculated values of actual generator voltage are indicated by the circle points falling on or near Curve 1 *B*.

Voltage Regulators. In case a generator voltage regulator is used in connection with a generator that loses load, the regulator will, of course, try to keep the voltage from rising. As soon as load is lost, the regulator contacts at once open and a block of resistance is inserted in the exciter field circuit. If a large amount of load is dropped on a waterwheel-driven generator, the generator voltage rises in spite of the fact that a block of resistance has been placed in the exciter field circuit, principally because flux change in the exciter and the generator is relatively slower than the speed change.

Curve *A* of Fig. 9 represents a voltage regulator test, as already mentioned. This curve is reproduced in Curve 4 of Fig. 2 for use in making calculations. For convenience, the starting point of the curve is raised to 111 per cent generator voltage and all other points are raised in the same proportion.

It was previously stated that Curve 3 of Fig. 2 shows how the generator voltage increases, assuming an over-speed on the exciter, but no over-speed on the generator. By combining Curve 3 and Curve 4, a resultant curve is obtained, as shown by Curve 5, which represents approximately the change in voltage when a load of 6100 kw., 0.83 power factor is dropped, a direct-connected exciter and a voltage regulator being used.

Curve 3 is used to take care of a 6100-kw. drop of load, as well as a 5900-kw. drop of load, because, if two curves were plotted, one would fall practically on the other. Now, increasing the voltage points on Curve 5, in accordance with the increase of speed, as shown by Curve 2 *A*, final calculated results are obtained as shown on the small triangles. These calculated points fall reasonably close to the test Curve 2 *B*.

Amount and Power Factor of Load Dropped. The per cent voltage regulation of a generator and the per cent speed regulation of a turbine being greater for full load than for part load, it is obvious that the loss of full load on a generator will cause a greater rise in voltage than dropping part load.

As the power factor of a load being furnished by a generator is decreased below unity (assuming constant kw. output), the field excitation, the kv-a. output, and the internal generated voltage increase. Therefore, the lower the power factor of the load dropped, the greater will be the rise in voltage.

Conclusions

It is not considered good practise to subject a transmission system to high over-voltages, especially if they are of long duration, because such over-voltage might cause damage to the generators, motors, transformers, lightning arresters, lines, insulators, and other equipment connected to the system.

Each piece of apparatus is designed for a particular maximum voltage, should be tested in accordance with A. I. E. E. Standardization Rules, and should operate continuously and successfully at that voltage under normal operating conditions. If the voltage is increased above normal, apparatus or equipment may or may not fail, according to the following factors:

1. Maximum over-voltage obtained.
2. Duration of over-voltage, taking into consideration the speed with which the voltage is increased or decreased.
3. Factor of safety in insulation and design of apparatus or equipment.

In other words, the time element of over-voltage must be taken into consideration as well as the maximum overvoltage. For example, a piece of apparatus may withstand an impulse voltage of double normal or more, when the duration of the impulse is a fraction of a cycle, but may fail if subjected to a voltage of much less value when applied continuously for several seconds at normal frequency.

In general, it is desirable to design any piece of apparatus so that it has as high a factor of safety against failure as is consistent with an economical design. The proper balance between factor of safety and economy of design depends largely on the principle underlying the design. In some kinds of apparatus, such as transformers, a high factor of safety is possible; in others, as lightning arresters, the same high degree of safety with over-voltage is incompatible with the proper function of the device.

An attempt to capitalize the factor of safety by operating a piece of apparatus at voltages above normal should never be made. Furthermore, it should not be assumed that the factor of safety will take care of any over-voltage that may exist momentarily on a system.

Although the apparatus treated thus may not fail immediately, the insulation or other parts may be weakened, so that by repeating or continuing the conditions of over-voltage, eventual failure is invited.

Total loss of load, and therefore dangerous over-voltage, may occur on any hydroelectric station having only one or two outgoing lines. If all, or nearly all, of the power is fed out from the station over one line, then in case of trouble it is quite possible that load on this line will be lost, particularly if the line is adequately protected by relays. If a station has two outgoing lines, both line breakers may occasionally trip automatically; also, if two outgoing lines are used, one line may be under repair, in which case all of the power would be transmitted over the second line. The situation would then be the same as though only one line existed.

When the load is fed out over three or more lines, there is much less likelihood of complete loss of load; therefore, the same precautions are not as essential as in the case of stations having only one or two circuits.

The contact of the over-speed and the over-voltage relays may be connected either in multiple or in series. If they are connected in multiple, the over-voltage relay should be given a sufficiently high setting to prevent it operating in case of ordinary switching surges. If the contacts are connected in series, the over-voltage, as well as the over-speed relay, may be given a rather low setting.

Discussion

H. W. Smith: The paper by Mr. Burnham is valuable in that it gives us actual tests on the over-voltages due to over-speeding of waterwheel generators. This problem has also been encountered by the Niagara Falls Power Company who have had lightning arresters fail due to the rise in voltage on dropping of load. Tests have shown that with load suddenly dropped, the generator voltage has increased from 12,000 to 21,000 volts. There was an instantaneous increase up to about 30 per cent above normal voltage. An over-voltage relay has been used to correct this difficulty, and the primary relay of the standard induction feeder regulator has been used as the voltage relay. This relay operates in about ten cycles of a 25-cycle system, and has been set to operate at 30 per cent above normal voltage.

At the Mitchell Dam plant of the Alabama Power Company,

the combination of over-voltage and over-frequency relays is used.

W. F. Dawson: There seems to be a difference in practise in respect to waterwheel governing. We in this country do not, so far as I know, provide by-passes to the penstock. Therefore it is necessary to have the governors operate very slowly. Otherwise the inertia of the water column would destroy the penstock. I do not know how far they have carried the practise, but I happened to be in England about eighteen years ago when a prominent London firm was asking for tenders for d-c. generators to be connected with water-wheels at the Lockleven plant of the British Aluminum Company. Following our American practise, I designed the proposed d-c. generators for about 50 per cent overspeed. It is the custom of consulting engineers in this country to require that generators and water-wheels be perfectly safe from mechanical overspeed stresses, at the anticipated runaway speed of the water-wheels. I told the consulting engineer that we had made such provision in the machines upon which we were tendering, and he was surprised.

He said, "We do not have to allow for that. Our waterwheel builders provide by-passes about the penstock, so that the governors can operate with sufficient rapidity to prevent overspeeding."

That is the only case I have ever had brought to my attention suggesting that by-passes were provided. If any waterwheel designers are here, we should have information from them, because it is certainly a tremendous handicap to the designers of generators for waterwheel plants, not to speak of the bad effect on over-voltage, to have to provide for from 50 to 75 per cent over-speed.

I realize, of course, that by-passes mean increased capital account, but the high over-speeding that has to be provided for also means big increase in the cost, not to speak of the disadvantage due to high over-voltage.

H. C. Don Carlos: I should like to correct the impression which might be gained from the last remarks, which intimate that pressure-regulating valves are not commonly used in this country. I think that a large majority of the high-head plants in this country are designed to use relief valves which are operated from the governor mechanically to give a by-pass in the case of heavy load rejections, which would tend to produce a heavy pressure rise in the penstock.

There is another factor which I believe has not been mentioned in the paper or the discussion, which should not be overlooked in a consideration of the over-speed of hydroelectric units, that is, the characteristic of the Francis-type turbine itself, which protects it against an over-speed of more than 65 to 70 per cent. Without any governors at all, most water wheels of this type will not attain an over-speed of more than 65 to 70 per cent on account of the choking of the water in the wheel.

E. J. Burnham: It has been suggested that resistance might be placed in the exciter field, and also in the generator field, in order to check the rise of voltage on a generator that has lost load.

Curve *a*, Fig. 9, of the paper shows the way generator voltage decreases when resistance is placed in the exciter field circuit. As the resistance in the field circuit is increased, Curve *a* approaches Curve *b* as the limit.

The results of inserting resistance in the generator field circuit at the time of dropping load would be represented by a curve lying between Curve *b* and Curve *c*, of Fig. 9. The method of inserting resistance in the generator field circuit could easily be adopted in cases where face-plate regulators are used.

Regarding the time of reaching maximum speed, after full load has been dropped, the time of three seconds is not uncommon on waterwheels of ordinary design, as shown by Curve *D*, of Typical Water Wheel Characteristics, Fig. 16.

The water-turbine characteristic curves shown by Fig. 16 apply, in a general way, to water turbines of different sizes, and used under different conditions, because, taking into consideration the different factors, such as size of turbine, length of penstock, and $W R^2$ of revolving parts, the results will be approximately the same in any case.

In accordance with Mr. Don Carlos' remarks, by-passes are commonly used in this country for stations having high heads.

The Loaded Submarine Telegraph Cable

BY OLIVER E. BUCKLEY[1]
Member, A. I. E. E.

Synopsis.—*With an increase of traffic carrying capacity of 300 per cent over that of corresponding cables of the previous art, the New York-Azores permalloy-loaded cable marks a revolution in submarine cable practise. This cable represents the first practical application of inductive loading to transoceanic cables. The copper conductor of the cable is surrounded by a thin layer of the new magnetic material, permalloy, which serves to increase its inductance and consequently its ability to transmit a rapid succession of telegraph signals.*

This paper explains the part played by loading in the operation of a cable of the new type and discusses some of the problems which were involved in the development leading up to the first commercial installation. Particular attention is given to those features of the transmission problem wherein a practical cable differs from the ideal cable of previous theoretical discussions.

Brief mention is made of means of operating loaded cables and the possible trend of future development.

* * * * *

THE announcement on September 24, 1924, that an operating speed of over 1500 letters per minute had been obtained with the new 2300-mile New York-Azores permalloy-loaded cable of the Western Union Telegraph Company brought to the attention of the public a development which promises to revolutionize the art of submarine cable telegraphy. This announcement was based on the result of the first test of the operation of the new cable. A few weeks later, with an improved adjustment of the terminal apparatus, a speed of over 1900 letters per minute was obtained. Since this speed represents about four times the traffic capacity of an ordinary cable of the same size and length, it is clear that the permalloy-loaded cable marks a new era in transoceanic communication.

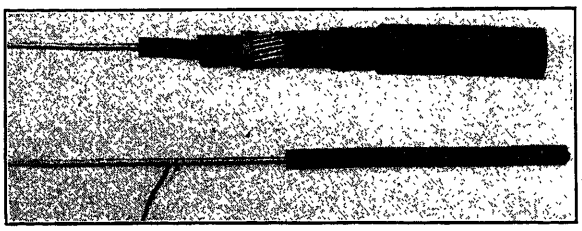

FIG. 1—PERMALLOY-LOADED CABLE
Above, section of deep sea type showing construction.
Below, section of core showing permalloy tape partly unwound.

The New York-Azores cable represents the first practical attempt to secure increased speed of a long submarine telegraph cable by inductive loading and it is the large distributed inductance of this cable which is principally responsible for its remarkable performance. This inductance is secured by surrounding the conductor of the cable with a thin layer of permalloy. Fig. 1 shows the construction of the deep sea section of the cable. In appearance it differs from the ordinary type of cable principally in having a permalloy tape, 0.006 in. thick and 0.125 in. wide, wrapped in a close helix around the stranded copper conductor.

Permalloy, which has been described by Arnold and Elmen[2], is an alloy consisting principally of nickel and iron, characterized by very high permeability at low magnetizing forces. The relative proportion of nickel and iron in permalloy may be varied through a wide range, or additional elements, as for example, chromium, may be added to secure high resistivity or other desirable properties. On account of its extremely high initial permeability, a thin layer of permalloy wrapped around the copper conductor of a cable greatly increases its inductance even for the smallest currents.

In the case of the New York-Azores cable the permalloy tape is composed of approximately 78½ per cent nickel and 21½ per cent iron and gives the cable an inductance of about 54 millihenries per nautical mile. An approximate value of the initial permeability of the permalloy in that cable may be obtained by assuming the helical tape replaced by a continuous cylinder of magnetic material of the same thickness. This material would have to have a permeability of about 2300[3] to give the observed inductance. A better appreciation of the extraordinary properties of the new loading material may be obtained by comparing this permeability with that which has previously been obtained with iron as the loading material. The Key West-Havana telephone cables are loaded with 0.008-in. diameter soft iron wire. The permeability of this wire, which was the best which could be obtained commercially when that cable was made, is only about 115, or approximately one-twentieth of that of the permalloy tape of the New York-Azores cable.

The proposal to use permalloy loading to increase the

2. *Journ. Franklin Inst.*, Vol. 195, pp. 621-632, May 1923.

3. The true initial permeability is slightly higher. To compute it, account must be taken of the fact that, contrary to what has been sometimes assumed, the magnetic lines of induction in the tape do not form closed loops around the wire but tend to follow the tape in a helical path. The pitch of the helical path of the lines of induction is slightly less than that of the permalloy tape with the result that a line of induction takes a number of turns around the conductor, then crosses an airgap between two adjacent turns of tape and continues along the tape to a point where it again slips back across an airgap. O. E. Buckley, British Patent No. 206,104, March 27, 1924; also K. W. Wagner, *E. N. T.*, Vol. I, No. 5, p. 157, 1924.

speed of long telegraph cables was one outcome of an investigation undertaken by the author, soon after the war, to determine whether some of the new methods and materials developed primarily for telephony might not find important application to submarine telegraphy. In the subsequent development of the permalloy loaded cable a large number of new problems, both theoretical and practical, had to be solved before the manufacture of a cable for a commercial project could be undertaken with reasonable assurance of success. The problems encountered were of three principal kinds. First was that of the transmission of signals over a cable having the characteristics of the trial conductors made in the laboratory. Although the theory of transmission over a loaded cable had been previously treated by others, the problem considered had been that of an ideal loaded cable with simple assumptions as to its electrical constants and without regard to the practical limitations of a real cable. The second class of problems had to do with the practical aspects of design, manufacture, and installation. In this connection an extensive series of experiments was conducted to determine the

means required to secure, at the ocean bottom, the characteristics of the laboratory samples on which the transmission studies were based. Among the numerous problems which arose in this connection were those concerned with protecting the copper conductor from any possible damage in the heat-treating operation which was necessary to secure the desired magnetic characteristics, and those concerned with protecting the strain-sensitive permalloy tape from being damaged by submerging the cable to a great depth. The third class of problems had to do with terminal apparatus and methods of operation. The prospective speed of the new cable was quite beyond the capabilities of standard cable equipment and, accordingly, new apparatus and operating methods suited to the loaded cable had to be worked out. In particular it was necessary to develop and construct instruments which could be used to demonstrate that the speed which had been predicted could actually be secured. The success of the investigations along all three lines is attested by the results which were obtained with the New York-Azores cable. Fig. 2 shows a section of cable recorder slip, the easily legible message of which was sent from Horta, Fayal, and received at New York at a speed of 1920 letters per minute.

It is principally with regard to the first of these classes of problems, that of the transmission of signals, that the following discussion is concerned. No attempt will be made here to discuss the details of design and development of the physical structure of the cable, nor will there be given a detailed description of the operating results or how they were obtained; these subjects must be reserved for later publication. It is desired in what follows to explain how inductive loading improves the operation of a submarine cable and to point out some of the problems concerned with the transmission of signals which had to be considered in engineering the first long loaded cable.

In order to understand the part played by loading in the transmission of signals, it is desirable first to review briefly the status of the cable art prior to the introduction of loading, and to consider the factors then limiting cable speed and the possible means of overcoming them. A cable of the ordinary type, without loading, is essentially, so far as its electrical properties are concerned, a resistance with a capacity to earth distributed along its length. Although it does have some inductance, this is too small to affect transmission at ordinary speeds of operation except on cables with extremely heavy conductors. The operating speed of a non-loaded cable is approximately inversely proportional to the product of the total resistance by the total capacity; that is,

$$S = \frac{k}{C R l^2}$$

where C is capacity and R resistance per unit length, and l is the length of the cable. The coefficient, k, is generally referred to as the speed constant. It is, of course, not a constant since it depends on such factors as terminal interference and method of operation, but is a convenient basis for comparing the efficiency of operation of cables of different electrical dimensions. As the technique of operating cables has improved, the accepted value of k has increased, its value, at any time, being dependent on the factor then limiting the maximum speed obtainable. This factor has, at times, been the sensitiveness of the receiving apparatus, at other times, the distortion of signals, and in recent years, interference. During a great part of the history of submarine cable telegraphy, distortion was considered the factor which limited the speed of operation of long cables and on this account most of the previous discussions of submarine cable transmission have been concerned principally with distortion and means for correcting it. As terminal apparatus was gradually

improved, means of correcting distortion were developed which practically eliminated distortion as an important factor in the operation of long cables. With distortion thus eliminated, the speed was found to be limited principally by the sensitiveness of the receiving apparatus. This limit was, however, in turn eliminated by the development of signal magnifiers. During recent years, in which numerous cable signal magnifiers have been available and methods of correcting distortion have been understood, the only factor limiting cable speed has been the mutilation of the feeble received signals by interference. Most cables are operated duplex, and in these, the speed is usually limited by interference between the outgoing and incoming signals. In cables operated simplex, and also in cables operated duplex where terminal conditions are unfavorable, speed is limited by extraneous interference which may be from natural or man-made sources and which varies greatly in different locations. The strength of the received current must, in either case, be great enough to make the signals legible through the superposed interference current. Owing to the

b. Ideal loaded cable
c. Real loaded cable (approximate)

rapidity with which the received signal amplitude is decreased as the speed of sending is increased, the limiting speed is quite sharply defined by the interference to which the cable is subject.

With the speed of operation thus limited, there were two ways in which the limiting speed could be increased; the interference could be reduced, or the strength of signals made greater. No great reduction in interference due to lack of perfect duplex balance could be expected, as balancing networks had already been greatly refined. Extraneous interference in certain cases could be reduced by the use of long, properly terminated sea-earths. The signal strength could be increased either by increasing the sending voltage or by decreasing the attenuation of the cable. Nothing at all is gained, however, by increasing the voltage in duplex operation where lack of perfect duplex balance limits the speed, and in simplex operation any gain from raising the voltage is obtained at the cost of increased risk to the cable, the sending voltage being usually limited to about 50 volts by considerations of safety. The attenuation of the cable could be reduced and the strength of the signal increased by use of a larger copper conductor or by using thicker or better insulating material. None of these possible improvements, however, seemed to offer a prospect of very radical advance in the art.

In telephony, both on land and submarine lines, an advantage had been obtained by adding inductance[4] in either of two ways, by coils inserted in series with the line or by wrapping the conductor with a layer of iron. The insertion of coils in a long deep-sea cable was practically prohibited by difficulties of installation and maintenance. Accordingly, only the second method of adding inductance, commonly known as continuous loading, could be considered for a transoceanic telegraph cable and it is primarily with regard to continuous loading that the following discussion is concerned.

Most of the proposals to load telegraph cables have had the object of reducing, or eliminating, distortion, and accordingly most of the mathematical treatments of loading have been from that point of view. The reduction of distortion is, however, not the only benefit to be obtained from loading and, in fact, may not always be secured in the high-speed operation of a loaded cable. The principal benefit of loading from the practical standpoint is to decrease the attenuation of the signals so that for a given frequency more current will be received or so that the minimum permissible current may be received with a greater speed of signaling. From the mathematical standpoint, there are two ways of treating the problem of the loaded

4. The idea of improving the transmission of signals over a line by adding distributed inductance to it originated with Oliver Heaviside in 1887, (*Electrician*, Vol. XIX, p. 79, and *Electromagnetic Theory*, Vol. 1, p. 441, 1893), who was the first to call attention to the part played by inductance in the transmission of current impulses over the cable. He suggested, as a means for obtaining increased inductance, the use of iron as a part of the conductor or of iron dust embedded in the gutta percha insulation. He also proposed inserting inductance coils at intervals in a long line. Other types of coil loading were proposed by S. P. Thompson (British Patent 22,304—1891, and U. S. Patents 571,706 and 571,707—1896), and by C. J. Reed (U. S. Patents 510,612 and 510,613—1893). M. I. Pupin (A. I. E. E. Trans., Vol. XVI, p. 93, 1899, and Vol. XVII, p. 445, 1900) was the first to formulate the criterion on the basis of which coil loaded telephone cables could be designed. Continuous loading, by means of a longitudinally discontinuous layer of iron covering the conductor, was proposed by J. S. Stone in 1897 (U. S. Patent 578,275). Breisig (*E. T. Z.*, Nov. 30, 1899) suggested the use of an open helix of iron wire wound around the conductor and Krarup (*E. T. Z.*, April 17, 1902) proposed using a closed spiral so that the adjacent turns were in contact. J. H. Cuntz (U. S. Patent 977,713 filed March 29, 1901) proposed another form of continuous loading. Recent general discussion of loaded telegraph cable problems has been given by Malcolm (Theory of Submarine Telegraph and Telephone Cable, London, 1917), and by K. W. Wagner, (E. N. T., Oct. 1924).

cable: first, with regard to the transmission of a transient impulse, and second, with regard to setting up steady alternating currents of definite frequency. In the ultimate analysis the solution of either problem can be got from the other. However, for practical purposes they are two distinct means of attack. The choice of the one to be used depends on the object to be secured. If one is concerned primarily with the effect of the cable on the wave shape of the signal transmitted over it, it is fairly obvious that the transient treatment has advantages. If, however, one is concerned only with the strength of the received signal, as is the case if there is assurance that the signal shape can, in any event, be corrected by terminal networks, then the steady state treatment is sufficient and much more convenient to apply. In the case of the real loaded cable the complete transient solution is extremely complex and the steady state treatment relatively simple. The solution of the transient problem of an ideal loaded cable is, however, very valuable to give a physical picture of how inductive loading aids the high speed transmission of signals.

The transient solution of the problem of an ideal heavily loaded cable has been worked out by Malcolm[5] and more rigorously by Carson,[6] who have determined the curve showing the change of current with time at one end of the cable if a steady e. m. f. is applied at zero time between the cable and earth at the distant end. Such a curve is called an "arrival curve" and for an ideal loaded cable comprising only constant distributed resistance, capacity and inductance may have a form like that shown in Curve *b* of Fig. 3, which is to be compared with Curve *a*, which is the arrival curve of a non-loaded cable. The straight, vertical part of Curve *b* represents the "head" of the signal wave which has traveled over the cable at a definite speed and with diminishing amplitude. The definite head of the arrival curve is the most striking characteristic difference between the ideal loaded and the non-loaded cable. In the latter, as is evident from Fig. 3, the current at the receiving end starts to rise slowly almost as soon as the key is closed at the transmitting end. When an e. m. f. is applied to the sending end of the non-loaded cable, a charge spreads out rapidly over the whole length, the receiving end charging up much more slowly than the sending end on account of the resistance of the intervening conductor. Hence, if a signal train, consisting of rapidly alternating positive and negative impulses, is applied to the sending end, the effect at the receiving end of charging the cable positively is wiped out by the succeeding negative charge before there has been time to build up a considerable positive potential and the successive alternating impulses thus tend to annul each other. In the loaded cable the effect of inductance is to oppose the setting up of a current and to maintain it once it has been established, and thus to maintain definite wave front as the signal impulse travels over the cable. Hence, with inductive loading, the strength and individuality of the signal impulses are retained and a much higher speed of signaling is possible. It should be noted that by speed of signaling is meant the rapidity with which successive impulses are sent and not the rate at which they travel over the cable. This speed of travel is actually decreased by the addition of inductance, about one third of a second being required for an impulse to traverse the New York-Azores cable from end to end.

It should be noted that Curve *b* of Fig. 3 is for an ideal loaded cable in which the factors of resistance, capacity, and inductance are constant. In a real loaded cable none of these factors are constant and the arrival curve cannot be simply and accurately computed. Even the capacity which is usually assumed as constant for real cables, varies appreciably with frequencies in the telegraph range, and, owing to the fact that gutta percha is not a perfect dielectric material, its conductance, which is also variable with frequency, must be taken into account. Although the inductance of the cable is substantially constant for small currents of low frequency, it is greater for the high currents at the sending end of the cable on account of the increase of magnetic permeability of the loading material with field strength and is less at high frequencies than at low on account of the shielding effect due to eddy currents. The resistance is highly variable since, in addition to the resistance of the copper conductor, it comprises effective resistance due to eddy currents and hysteresis in the loading material, both of which vary with frequency and current amplitude. Furthermore, there is variable inductance and resistance in the return circuit outside the insulated conductor which must be taken into account. Although it is very difficult to compute the exact arrival curve of a cable subject to all of these variable factors, an approximate calculation in a specific case, like that of the New York-Azores cable, shows that the arrival curve has the general shape of Curve *c* of Fig. 3. It will be noticed that although this arrival curve lacks the sharp definite head, characteristic of the ideal loaded cable, it still has a relatively sharp rise and that the time required for the impulse to traverse the cable is not greatly different from that of the ideal loaded cable.

Although it is difficult to take exact account of the variable characteristics of the loaded cable in the solution of the transient problem, it is easy to take account of them in the steady state or periodic analysis by means of well-known methods. If a steady sinusoidal voltage, V_s, is applied at one end of the cable, the resulting voltage, V_r, at the distant end, will be given by the equation

$$V_r = k\, V_s\, \epsilon^{-Pl}$$

where l is the length, P the propagation constant of the cable, and k a constant which depends on the terminal

5. Theory of the Submarine Telegraph and Telephone Cable, London, 1917.

6. TRANS. A. I. E. E., Vol. 38, p. 345, 1919.

impedance and which is unity in case the cable is terminated at the receiving end in its so-called characteristic impedance. The propagation constant is given by the formula,

$$P = \sqrt{(R + i\,p\,L)\,(G + i\,p\,C)} = \alpha + i\,\beta$$

where R is the resistance, L is the inductance, G is the leakance, C is the capacity per unit length, and p is $2\,\pi$ times the frequency. The real part of the propagation constant, α, is called the attenuation constant and the imaginary part, β, the wave length constant. By separating α and β, the amplitude and phase displacement of the received voltage relative to the sent voltage may be computed for any particular frequency and the behavior of a complex signal train may be worked out by analyzing it into its Fourier components and treating them separately. The phase shift is, however, of importance mainly as regards the shape of the received signals, and their amplitude may, in general, be obtained from the attenuation constant alone. Thus if it is known that the signal shape can, in any case, be corrected by terminal networks, there is no need to be concerned with more than the attenuation constant to compute the speed of the cable.

In the case of a cable of the permalloy-loaded type, α is given with an approximation[7] sufficiently close for the purposes of this discussion by the equation

$$\alpha = \frac{1}{2}\sqrt{\frac{C}{L}}\left(R + \frac{G}{C}\,L\right)$$

For the purpose of computing R, it is convenient to separate it into its components, giving

$$\alpha = \frac{1}{2}\sqrt{\frac{C}{L}}\left(R_c + R_e + R_s + R_h + \frac{G}{C}\,L\right)$$

where

R_c = copper resistance per unit length
R_e = eddy current resistance per unit length
R_s = sea return resistance per unit length
R_h = hysteresis resistance per unit length

The copper resistance, R_c, is that determined by a direct-current measurement of the loaded conductor, since the resistance of the loading tape is so high and its length is so great that the current flowing longitudinally through it may be safely neglected.

The eddy current resistance, R_e, is given approximately by the formula,

$$R_e = \frac{m\,\mu^2\,t^3\,f^2}{\rho\,(d - t)}$$

where t is the thickness or diameter of the loading tape or wire, d is the outside diameter of the loaded conductor, f is the frequency, ρ is the resistivity of the loading material, μ is its magnetic permeability, and m is a constant which depends on the form of the loading material and is, in general, greater for tape than for wire loading. Although it is possible to compute a value of m, the value found in practise is always larger than the theoretical value, which is necessarily based on simple assumptions and does not take into account such a factor as variation of permeability through the cross-section or length of the loading material. Accordingly, it is necessary for any particular type of loaded conductor to determine m experimentally.

The sea-return resistance may safely be neglected in the computation of slow speed non-loaded cables, but it is a factor of great consequence in the behavior of a loaded cable. By sea-return resistance is meant the resistance of the return circuit including the effect of the armor wire and sea water surrounding the core of the cable. Although the exact calculation[8] of this resistance factor is too complex to be discussed here, the necessity of taking it into account may be quite simply explained. Since the cable has a ground return, current must flow outside the core in the same amount as in the conductor. The distribution of the return current is, however, dependent on the structure of the cable as well as on the frequencies involved in signaling. If a direct current is sent through a long cable with the earth as return conductor, the return current spreads out through such a great volume of earth and sea water that the resistance of the return path is negligible. On the other hand, if an alternating current is sent through the cable, the return current tends to concentrate around it, the degree of concentration increasing with the frequency. With the return current thus concentrated the resistance of the sea water is of considerable consequence. It is further augmented by a resistance factor contributed by the cable sheath. This may be better understood by considering the cable as a transformer of which the conductor is the primary and the armor wire and sea water are each closed, secondary circuits. Obviously, the resistances of the secondary circuits of armor wire and sea water enter into the primary circuit and hence serve to increase the attenuation. The presence of the armor wires may thus be an actual detriment to the transmission of signals.

To take account of the hysteresis resistance, R_h, and also of the increased inductance and eddy current resistance at the sending end of the cable, it is most convenient to compute the attenuation of the cable for currents so small that R_h may be safely neglected. The attenuation thus computed is that which would be obtained over the whole cable if a very small sending voltage were used. The additional attenuation at the sending end for the desired sending voltage may then be approximated by computing successively from the sending end the attenuation of short lengths of cable over which the current amplitude may be considered constant, the attenuations of separate lengths being added together to give the attenuation of that part of

7. For accurate computation of attenuation the complete formula for α must be used.

8. See Carson and Gilbert, *Jour. Franklin Inst.*, Vol. 192, p. 705, 1921, and *Electrician*, Vol. 88, p. 499, 1922.

the cable in which hysteresis cannot be neglected. In this computation, account must, of course, be taken of the increased inductance and eddy current resistance accompanying the higher currents at the sending end.

Having calculated or obtained by measurement the several resistance factors, and knowing the capacity, leakance, and inductance, the whole attenuation of a cable for any desired frequency may be computed and a curve drawn showing the variation of received current with frequency for a given sending voltage. This relation for a particular case is shown in Curve *c* of Fig. 4. Curve *a* shows, for comparison, the relation between frequency and received current of a non-loaded cable of the same size, that is, a cable having a conductor diameter the same as that of the loaded conductor and having the same weight as gutta percha. Curve *b* shows

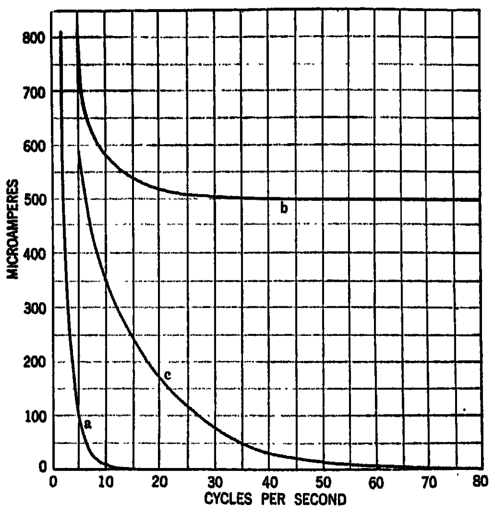

FIG. 4—RECEIVED CURRENT VS. FREQUENCY

a. Non-loaded cable
b. Ideal loaded cable
c. Real loaded cable

the behavior of an ideal loaded cable having the same inductance, capacity, and d-c. resistance as the real loaded cable of Curve *c*, but in which the leakance and alternating current increments of resistance are assumed to be zero.

Now, if the level of interference through which the current must be received is known, the maximum speed of signaling for the loaded cable may be obtained from Curve *c*. It is that speed at which the highest frequency necessary to make the signals legible is received with sufficient amplitude to safely override the superposed interference. Just what the relation of that frequency is to the speed of signaling cannot be definitely stated, since it depends on the method of opertion and code employed as well as on the desired perfection of signal shape. J. W. Milnor[9] has suggested that for cable code operation and siphon recorder reception a fair value is about 1.5 times the fundamental frequency of the signals, that is, the fundamental frequency when a series of alternate dots and dashes is being sent.

By referring again to the equation for α, it can now be explained why high permeability is a necessary characteristic of the loading material if benefit is to be obtained from continuous loading. The addition of the loading material has two oppositely directed effects; on the one hand it tends to improve transmission by increasing the inductance and consequently decreasing the attenuation, and on the other hand it tends to increase the attenuation by increasing the effect of leakance and by the addition of resistance. Not only are the hysteresis and eddy-current factors of resistance added by the loading material, but it must also be looked on as increasing either the copper resistance or the capacity on account of the space it occupies. Generally it is more convenient to look on the loading material as replacing some of the copper conductor in the non-loaded cable with which comparison is made, since by so doing all of the factors outside of the loaded conductor are unchanged. Now, if the loading material is to be of any benefit, the decrease in attenuation due to added inductance must more than offset the increase due to added resistance, including the added copper resistance due to the substitution of loading material for copper. In the limiting case the lowest permeability material which will show a theoretical advantage from this point of view is that which, as applied in a vanishingly thin layer, gives more gain than loss. For any particular size and length of cable there is a limiting value of permeability which will satisfy this condition, this limiting value being greater the longer the cable and the smaller the diameter of its conductor.[10] For transatlantic cables of sizes laid prior to 1923, the minimum initial permeability required to show an advantage is higher than that of any material known prior to the invention of permalloy. Actually a considerably higher permeability than this theoretical minimum was, of course, required to make loading an economic advantage, since there are practical limits to the thickness of loading material and since the cost of applying it has also to be taken into account. Further, there are limits on methods of operation, imposed by loading, which necessitate still higher permeability to make loading worth while.

Since the addition of loading has two opposite tendencies in its effect on attenuation, the practical design of the cable must be based on a compromise between them. Thus, to secure the maximum gain from loading a cable of a given size, the loading material should be chosen of such a thickness that the gain due to increased inductance from a slight increase of thickness just offsets the loss due to increased resistance and dielectric leakance. In practise, of course, economic considerations of the cost of various thicknesses of loading must also be taken into account.

9. JOURNAL A. I. E. E., Vol. 41, p. 118, 1922; TRANSACTIONS A. I. E. E., Vol. 41, p. 20, 1922.

10. O. E. Buckley, British Patent No. 184,774, 1923.

In designing the New York-Azores cable some assumption had to be made as to the extraneous interference which would be encountered. Theoretical considerations led to the belief that the loaded cable would be no more subject to external interference than non-loaded cables. It even appeared that it would be less affected by some types of interference, for, owing to the shorter wave length for a given frequency, a disturbance which affects a great many miles of cable simultaneously is less cumulative in its effect at the terminal of a loaded than a non-loaded cable. A reasonable assumption seemed to be that the total overall attenuation which could be tolerated for the loaded cable was at least as great as that which experience had shown to be permissible for simplex operation of non-loaded cables. Of course, this maximum permissible attenuation depends on conditions of terminal interference, and no fixed value can be given as applicable to all cables. However, for average conditions of terminal interference in locations free from power-line disturbances, and where the cable lies in relatively deep water near to its terminal landing, a reasonable value of total attenuation constant for the fundamental frequency of cable code is about 10 (86.9 T. U.) for recorder operation and about 9 (78.2 T. U.) for relay operation. These were the approximate values assumed for the New York-Azores cable and later experience has demonstrated that they were well justified.

Throughout all of the preceding discourse, it has been assumed that the relation between attenuation and terminal interference would limit the speed of simplex operation, rather than that distortion of signal shape would be the limiting factor. Although this is, in fact, the case with non-loaded cables,[11] it was not self-evident as regards the loaded cable, and to make reasonably certain that the speed could be determined from the attenuation-frequency relation required a demonstration that the signal distortion of a real loaded cable could be corrected by suitable terminal apparatus. One of the merits long claimed for loading was that it would reduce distortion and, indeed, an ideal loaded cable with constant inductance and without magnetic hysteresis, eddy current loss, dielectric leakance, and sea-return resistance would have very little distortion and would give a speed limited only by terminal apparatus. However, a real loaded cable, the inductance of which varies with both current and frequency and in which all the above noted resistance factors are present, may give, and in general will give when operated at its maximum speed, greater distortion of signals than a non-loaded cable.

To solve the question of distortion on a purely theoretical basis required consideration of the transmission of a transient over the loaded cable. This was made extremely difficult by the existence of numerous possible causes of signal distortion, the effects of which could only be approximated in the solution of the transient problem. In addition to the distortion resulting from the rapid increase of attenuation with frequency due to the various sources of a-c. losses, distortion peculiar to the magnetic characteristics of the loading material had also to be taken into account. There are several types of magnetic distortion worthy of consideration. First, there is the production of harmonics as a result of the non-linear magnetization curve of the loading material; second, there is a possible asymmetrical distortion due to hysteresis, and third, there is a possible modulation resulting from the superposition of one signal upon another, which is, in effect, a modulation of the head of the wave of one impulse by the tail of the wave of a preceding impulse. The first two of these are effective at the sending end of the cable and the third near the receiving end.

A computation of distortion, including the peculiar magnetic effects, by a steady state, a-c. method, based on measurements of short loaded conductors, indicated that the cable should operate satisfactorily with ordinary sending voltages. Further evidence that none of these various types of distortion would be of serious consequence, and that the distortion of a loaded cable could be corrected by terminal apparatus, was obtained by experiments with an artificial line constructed to simulate closely, as regards electrical characteristics, the type of loaded conductor with which experiments were then being made. This artificial line was loaded with iron-dust core coils, which admirably served the purpose, not only as regards inductance and a-c. resistance but also as regards magnetic distortion. Iron dust is, of course, very different from permalloy in its magnetic characteristics. But owing to the large number of turns on a coil, it is operated at much higher field strengths and on a part of the magnetization curve corresponding approximately to that at which permalloy is operated on the cable. In fact the case for magnetic distortion was a little worse on the artificial line than in the then proposed cable. Fig. 5 shows an illustration of the artificial line, the coils of which are in the large iron pots and the resistance and paper-condenser capacity units of which are in the steel cases. This line was equivalent to a 1700-nautical-mile cable, loaded with 30 millihenries per nautical mile, and over it, legible signals were secured at speeds up to more than 2600 letters per min. Such a speed of operation was quite beyond the range of the then available telegraph instruments, and accordingly special transmitting and receiving instruments were required. The multiplex distributor, of the Western Electric printing-telegraph system, proved an excellent transmitter for experimental purposes, and for receiving, use was made of a combined vacuum-tube amplifier and signal-shaping network, the signals being recorded on a string

11. Recent work of J. R. Carson (U. S. Patent 1,315,539—1919) and R. C. Mathes (U. S. Patent 1,311,283—1919) has shown that with the combined use of vacuum tube amplifiers and distortion correcting networks, distortion in non-loaded cables can be compensated to any desired degree.

oscillograph. Fig. 6 shows part of a test message received over the loaded artificial cable at a speed of 2240 letters per min.

The results of the tests with the artificial loaded cable were entirely in agreement with the author's calculations, and showed that it was possible to obtain satisfactory signal shape with a coil loaded cable having a-c. resistance and distortion factors approximating those of the permalloy loaded cable. The exact

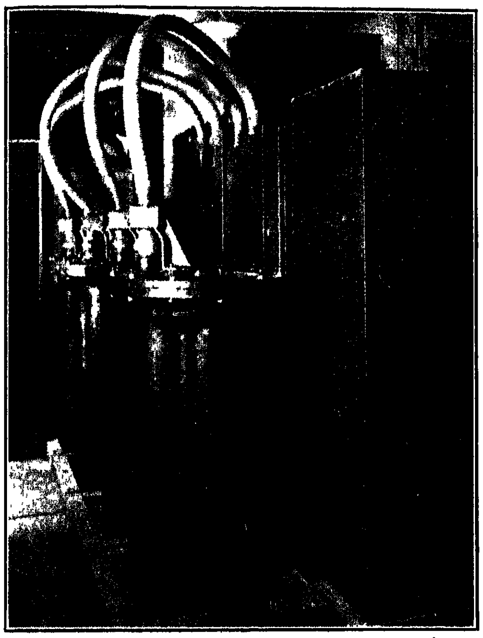

FIG. 5—LOADED ARTIFICIAL LINE

behavior of the proposed cable, including such factors as sea-return resistance and a somewhat variable distributed inductance, could not, of course, be duplicated without prohibitive expense. The approximation was considered, however, to be sufficiently good to justify proceeding with a loaded cable installation so far as questions of signal shaping were concerned. It is interesting to note that the factor which limited the operating speed of the artificial loaded cable was one which is not present in a continuously loaded cable but which possibly would be a serious factor in the operation of a coil loaded cable, namely, the oscillations[12] resulting from the finite size and separation of the inductance units.

With the completion of the artificial loaded cable tests, there was still one principal question of transmission which had to remain unanswered until a cable had been installed. This was the question of balancing the cable for duplex operation. Ordinary submarine cables are generally operated duplex, the total speed in the two directions being usually from about 1.3 to 2 times the maximum simplex or one-way speed. Except in cases where the external interference is very bad, the limiting speed of duplex operation is determined by the accuracy with which an artificial line can be made the electrical equivalent of the cable. Ordinarily, the artificial line is made up only of units of resistance and capacity arranged to approximate the distributed resistance and capacity of the cable. Sometimes inductance units are added to balance the small inductance which even a non-loaded cable has. In the actual operation of cables, artificial lines are adjusted with the greatest care and a remarkable precision of balance is obtained. This is necessary because of the great difference in current amplitude of the outgoing and incoming signals, the former being of the order of 10,000 times the latter. It is quite obvious that it will be much more difficult to secure duplex operation with a loaded cable than with one of ordinary type, since not only do the copper resistance and the dielectric capacity have to be balanced, but the artificial line must also be provided with inductance and a-c. resistance. Also the sea-return resistance and inductance which vary with frequency must be balanced.

In view of these difficulties, it will probably be impossible to get as great a proportionate gain from duplex operation of loaded cables as is secured with ordinary cables. However, it is quite evident that it will be possible to obtain duplex operation at some speed, since, with loaded as with non-loaded cables, the ratio of received-to-sent current increases rapidly as the speed is reduced, and on this account it is much easier to duplex the cable at low speeds than at high. To make duplexing worth while on a cable with approximately equal traffic loads in both directions, it is, in general, only necessary to get a one-way duplex speed half as great as the simplex speed. In fact, in some cases the operating advantages of duplex would warrant even a slower duplex speed. On the other hand, there are cables on which the traffic is largely unidirectional through most of the day and which would accordingly require a one-way duplex speed somewhat higher than half the simplex speed to justify duplex

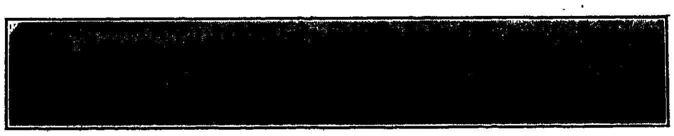

FIG. 6—TEST MESSAGE

Signals received April 16, 1920 over coil-loaded artificial line equivalent to a 1700 n. m. cable with 30 m. h./n. m. Speed 2240 letters per minute.

operation. Whether a sufficiently great speed of duplexing could be secured to justify designing a cable on the basis of duplex operation could not be judged in advance of the laying of the first cable, and accordingly it was decided to engineer that cable on the basis of simplex operation.

Although it was expected that the new cable might at first have to be operated simplex it should not be supposed that any great difficulty or loss of operating efficiency was anticipated on this account. The speed of the New York-Azores cable is so great that to realize its full commercial advantage practically requires

12. Carson, TRANS. A. I. E. E., Vol. 38, p. 345, 1919.

working it on a multi-channel basis, as, for example, with a Baudot code, multiplex system, similar to that used on land lines. Such a system may be conveniently adapted to automatic direction reversal and, with this modification, most of the common objections to simplex operation are removed. Indeed, simplex operation may in this case possess a real advantage over duplex, from the commercial point of view, since it permits dividing the carrying capacity of the cable most efficiently to handle the excess of traffic in one direction.

Although means for making efficient use of the loaded cable have been made available, it should be recognized that the method of operation best suited to satisfy commercial demands must be determined from future experience with cables of the new type. This is especially true with regard to relatively short cables. In this paper the discussion of the loaded cable problem has been confined wholly to the realm of long ocean cables where the limitations of the cable, rather than terminal equipment or operating requirements, determine the best design. This is the simplest case and the one which, at present, seems to show the greatest gain from loading. Where traffic requirements are limited and there is no prospect of ever requiring a speed higher than can be obtained with a non-loaded cable of reasonable weight, the advantage of loading is less and becomes smaller as the weight of non-loaded cable which will accomplish the desired results, decreases. It should not, however, be concluded that loading will not find important application to short cables. Many short cables are parts of great systems and must be worked in conjunction with long cables. In such cases it may pay to load short sections where loading would not otherwise be justified. Permalloy loading also offers great possibilities for multiple-channel carrier-telegraph operation on both long and short cables, and with this type of operation in prospect it is too early, now, to suggest limits to the future applications of permalloy to cables or to predict what will be its ultimate effect on transoceanic communication.

Discussion

W. C. Peterman: This paper treats of a phase of communication that apparently has not kept pace with the advances in other methods of communication. Numerous inquiries have been directed in recent years to the cause of this apparent lack of progress in the field of cable telegraphy. As a matter of fact, a very considerable progress has been made in the past 10 or 15 years. The improvements in this period, principally in the terminal apparatus, repeating apparatus, and operating methods, resulted in a substantial increase of speed and a reduction of operating cost. There were, among others, the introduction of a successful relay to automatically connect two cable sections, the development of an amplifier suitable for cable conditions, and the improvement in the design and use of artificial cables for duplexing.

During the past few years there has also been developed by the Western Union engineers, a system of repeating-cable signals which completely regenerates them as to shape and strength so that on leaving the repeating station they are as perfect as when originally sent. This system permits of the insertion of a number of repeaters in a circuit where previously one had been the limit. By this method, automatic through operation direct between New York and London was for the first time successfully accomplished. There has also been developed a special printing telegraph system which permits of a higher operating speed in letters per minute than can be obtained with the usual cable code which had heretofore been considered the fastest system for ocean cables. This printing method has proved highly successful on a through circuit from New York to London with duplex operation.

When the possibilities of this new type of cable, as outlined by Dr. Buckley, were presented to us, we were immediately interested. Our engineers went into the subject as presented to them, and came into entire agreement on all points. From then on our engineers checked over the designs and plans at every stage to satisfy themselves as to their correctness, for a submarine cable is such a large, long-time investment that every precaution must be taken to insure nothing having been overlooked. As an additional precaution a trial 120-mi. length of loaded cable was manufactured and laid in deep water off Bermuda. The results of tests made on this cable were in accordance with predictions from the previous laboratory tests and theoretical studies made by Dr. Buckley. The Western Union was satisfied with the results and proceeded to lay the 2300-mi. Azores cable. This was done without mishap and met all requirements. Dr. Buckley is to be congratulated on the conception of the application of a material of high permeability in ocean cables and on the successful development of the idea.

With this new cable, combining speed, accuracy, reliability, and the usual secrecy of cable messages, we are now, for the first time, linked by cable to Italy and Spain, and to these we hope in the near future to add Germany. At that time it is expected that this cable will be operated on the multiplex system with five or six channels. Three or four of these channels will be used by the Western Union, and it is planned that two or three channels will be used by the Commercial Cable Company under agreement with the Western Union. With the present plans, some of the channels will be operated directly from New York to Berlin and Hamburg without manual rehandling. One or more channels will terminate at the Azores. The channels assigned to the Commercial Cable Company will be operated directly from their office in New York to either Germany or the Azores; all this gives some idea of the flexibility of the multiplex system when used on such a cable.

But more important still, the confidence inspired by the performance of this cable has led the Western Union to order another similar loaded cable, this time to connect New York and London. The signals will be automatically repeated at Newfoundland and Penzance, England, so that there will be complete automatic, through operation between New York and London. This new loaded cable will have a still higher operating speed than the present loaded cable, being designed to transmit signals of frequencies up to 75 cycles per second, which corresponds to a speed of 2400 letters per minute with cable code.

We shall have to revise our ideas of cable telegraphy, for this speed is considerably higher than that at which most of the open-wire, land-line telegraph circuits in the United States are being operated today. This cable will probably require two overland circuits to carry its traffic from Penzance—the cable station on the coast of England—to London. Indeed, the traffic-carrying capacity of this cable will be so great that it will be nearly equal to the total capacity of our present seven cables to England. The addition of this cable alone will result in about a 40-per cent increase in the traffic-carrying capacity of all the present North Atlantic cable communication systems.

The operation of these cables with the Baudot code and with a number of channels, each with its own transmitter and printer, will place cable operation upon the same basis as our trunk land

lines, with all that that means in similarity of operating methods and apparatus. With this code there is also the possibility of automatically extending some or all channels of such cables by means of our existing land-line system directly to other parts of the United States. A new era is here; between points where the traffic is heavy, the old wavy line of the siphon recorder will gradually drop out of the picture.

E. B. Craft: I should like to correct one impression which may have been given by Dr. Buckley's paper. As he has described the problem of the loaded cable it looks too easy; it looks as if all that had been done was to wrap a permalloy tape around a copper wire and then make a high-speed cable of it.

I wish you might appreciate how much more there was involved in this accomplishment than can be brought out in such a brief paper as that to which you have just listened. Years of painstaking effort were required and difficulties were encountered at every step. Precautions had to be taken against any harmful mechanical and electrical effect which might be encountered in laying or operating a cable.

One very interesting feature of the New York-Azores cable which Dr. Buckley has not mentioned is the new type of balanced sea-earth which was developed after an extensive investigation of cable interference. This sea-earth almost completely eliminates the effect of local power disturbances and atmospherics and makes it possible to operate cables efficiently in the most unfavorable terminal locations.

When the development of the loaded cable was undertaken there were no means in sight for efficient operation of such a high-speed loaded cable, even if the problems of the cable itself could be solved. New operating methods and new methods to measure the electrical constants of a loaded cable had to be worked out and new instruments had to be developed for these purposes. When the cable was laid, these instruments were ready and within a few hours after the final splice was made, the successful operation of the cable was demonstrated. Almost every piece of apparatus used in the test and demonstration of the cable was new and specially developed for the purpose. A new type of cable transmitter, working with compressed air, was devised to send messages at speeds many times greater than would be permitted by any previously existing transmitter. A siphon recorder which would record messages at over 2500 letters per minute was devised and made ready for the test. But perhaps the greatest achievement in this connection was the signal-shaping amplifier. This represented an achievement comparable with that of the cable itself. In addition to apparatus for test and demonstration of the cable, operating systems suitable for commercial use were worked out and tested over an artificial line in the laboratory. All of this was done in advance of laying the first cable.

I hope that some of these accomplishments may later be subject to publication, and when all that was done to make the permalloy-loaded cable a success is known, I am sure that you will feel, as I do, no small satisfaction in its having been an American achievement.

Chas. A. Perkins: It has occurred to me to ask why the air-gap which occurs in this permalloy winding does not largely neutralize the effect of the high permeability of the material.

O. E. Buckley: Professor Perkins has asked why the air-gap between the adjacent turns of permalloy tape does not materially neutralize the effect of the high permeability of that metal. The answer is rather interesting and may possibly surprise some of you. The reason that the air-gap does not introduce much reluctance in the magnetic circuit is that the magnetic lines of induction are not single loops around the conductor, as has sometimes been assumed, but have the form of a helix which takes a large number of turns around the conductor before crossing an air-gap between adjacent turns of the permalloy tape. In the case of a conductor like that of the New York-Azores cable the lines of induction follow the permalloy tape very closely, the pitch of the screw of the lines of induction being only slightly less than the pitch of the tape, with the result that a line of induction follows the tape for about 20 turns around the conductor, then jumps an air-gap between two adjacent turns and continues following the tape in the same direction as before for another 20 turns, when it again slips back across an air-gap. This means that if the permalloy tape were strictly uniform and continuous from one end of the cable to the other and if the cable carried a steady, direct current and was not subject to the effect of the earth's field, the lines of induction would be continuous from one end of the cable to the other.

Law Description and Hypothesis in the Electrical Science[1]

BY M. I. PUPIN[2]

YOUR invitation to deliver the first Steinmetz lecture I consider a very great honor. The late Doctor Steinmetz was a dear friend of mine. I met him in Yonkers in 1889, and from that time on until his death we were tied to each other by bonds of personal sympathy and scientific interest, which was a source of uninterrupted pleasure to both of us.

This lecture is an attempt to describe briefly how Faraday and Maxwell, starting from definite laws which were discovered by experiment, created the modern Electromagnetic Theory by a prophetic use of description and hypothesis, and how this theory furnishes the foundation of the Science of Electrical Engineering.

Our knowledge of electrical phenomena began its career as a science when it started to build upon a foundation of a quantitative law. Coulomb's law marks, therefore, the beginning of the electrical science. It says that two electrical point charges in a vacuum act upon each other with a mechanical force which is equal to the product of the two charges divided by the square of the distance between them.

In its mathematical form Coulomb's law is identical with Newton's law of gravitational action. Many theorems which the mathematical physicists of the eighteenth and the beginning of the nineteenth centuries had developed in their analyses of gravitational fields of force were, apparently, directly applicable to the analysis of electrical fields. This was very fortunate, because it attracted some of the best mathematical minds of those days to the electrical science. This raised its standing among the sciences which it badly needed.

Newton's great essay, Principia Philosophiae Naturalis, published in the beginning of the eighteenth century, created a new school of natural philosophers which dominated during the eighteenth century the scientific mental attitude of the world. No natural philosopher of those days could expect to attract serious attention who departed from the rigorously mathematical methods of this school. Even so great a natural philosopher as Benjamin Franklin may be said to have been snubbed by the Royal Society, when it refused to publish in its transactions Franklin's communications describing his electrical experiments. These experiments, suggested by and clustering around Leyden jar discharges, had no obvious connection with the Newtonian school of natural philosophy of the eighteenth century and, therefore, the Royal Society failed to recognize their full significance. One may imagine how welcome Coulomb's law was to some natural philosophers of the eighteenth century, to whom Newton's Principia was as final as the book of Genesis is to some people of our own generation.

Faraday was the first to point out a fundamental difference between Newton's law of gravitational action and Coulomb's law of electrical action. The action of a gravitational mass upon another gravitational mass is not influenced by the medium separating the two, but the action of an electrical charge upon another electrical charge is influenced very much by the medium separating the two. Coulomb's law unaided by other considerations was unable to explain this difference. Faraday was the first to enter into these considerations, and his first guide may be said to have been a hypothesis which maintained that all electrical charges trace their origin to the molecules and atoms of material bodies, which in their normal state contain, according to Franklin, the same amounts of positive and negative charges. This hypothesis of the atomic origin of electrical charges was undoubtedly suggested by Faraday's classical studies of the behavior of electrolytes, which revealed a new truth, namely, that a definite electrical charge is attached to each valency of atoms. The granular structure of ordinary electrical charges and the whole modern electron theory was first foreshadowed in these experiments. But how did this hypothesis affect Coulomb's law of force between Coulomb charges which are surrounded by a material medium?

Consider the insulators. The hypothesis suggested that in an insulator each molecule contains a definite quantity of positive and an equal quantity of negative charge which can be separated from each other by the action of an external electrical force impressed upon them, but that the distance of separation cannot exceed the dimensions of the molecule. Adopting this picture of the electrical structure and behavior of insulators, there was readily deduced a modified form of Coulomb's law of force between charges separated by an insulating medium, and this modified form of Coulomb's law says: *The force between two point charges in an insulating material medium is equal to that in a vacuum divided by a constant, called the specific inductive capacity of the material medium.*

But experiment told us that the hypothesis mentioned above concerning the process of separating molecular charges and everything inferred from it can be only approximately true, because the

1. The first Steinmetz lecture delivered on May 8, 1925, before the Schenectady section of the American Institute of Electrical Engineers.

2. Of Columbia University, New York.

specific inductive capacity of material insulators is usually neither constant nor does it always have a definite meaning. This law, therefore, could not be taken as our infallible guide in the study of the electrical fields of force in material insulators. The question arose then: Is there any other law to which we can appeal for guidance? Faraday's study of the electrical action of insulators, a subject to which Benjamin Franklin first drew attention, showed a way leading to the answer of this question. This study suggested one of the two great foundation pillars of the modern electromagnetic theory, which I venture to describe here briefly.

Faraday's method of representing graphically the field of force of electrical charges is well known, and it finds its simplest illustration in the well known conical tubes of force drawn from a point charge as vertex and expanding into all space. We are also familiar with Faraday's tubes[3] of force for any distribution of electrical charges. Faraday's pictorial method of describing the field of force leads to the same numerical results as Coulomb's law when the surrounding medium is free space without any material bodies in it. When, however, the surrounding medium contains material insulators, Coulomb's law offers small assistance in our study when these insulators have a variable specific inductive capacity and deviate otherwise from the characteristics of an ideal dielectric. It will be pointed out below that there are electric and magnetic fields which are not due to charges and in which Coulomb's law is altogether inapplicable. Faraday's picture of the field in terms of the tubes of force suggested to Maxwell a new law of force which is broader than Coulomb's law both in its meaning and its applicability.

Faraday's ideas concerning the physical character of the tubes of force were a guide to Maxwell, whose earliest studies of electrical phenomena, while still an undergraduate at the University of Cambridge, related to Faraday's *Physical Lines of Force*. In these early studies Maxwell made wonderful attempts to show by imaginative description and ingenious mechanical models what he saw in Faraday's tubes. But all these things were only a temporary scaffolding around a new structure which Maxwell was building. When the structure was finished the scaffolding disappeared, and what do we see today? I shall try to answer this question.

In Maxwell's mind, just as in the mind of Faraday, the tubes of force were not mere geometrical pictures but represented physical entities capable of actions and reactions. Each volume element of a tube of electric force is, according to Faraday and Maxwell, the seat of an electrical reaction against the change of its density, that is, of the number of tubes per unit area. When the surrounding medium is a vacuum or an ideal insulator, that is, a dielectric with a constant specific inductive capacity, then the numerical value of this reaction can be calculated. According to Maxwell's hypothesis, the electrical reaction in this case per unit length and unit cross-section of the tube is equal to the density of the tubes in the direction in which the reaction is considered, divided by the specific inductive capacity. The hypothetical reaction had a most significant corollary; it located the energy of the field in the volume elements of the tubes of force and assigned to each element, per unit of volume, an amount proportional to the square of the density of the tubes of force at that volume element. Dynamically, therefore, there is a perfect resemblance between the field of electrical reactions in ideal insulators and the field of elastic reactions in the interior of an elastically strained body which obeys the so-called Hooke's law.

According to this view, the charges transmit their action through the volume elements of the tubes against the reaction of the tubes. *When the field of electrical force is in equilibrium the external actions coming from the electrical charges and the internal electrical reactions of the tubes are equal and opposite to each other at every point of space.* This form of statement is suggested by Newtonian dynamics and furnishes a law which conforms to Newton's third axiom. It is different from Coulomb's law in form and meaning, and it holds good no matter how the impressed forces are generated or what the physical character of the material bodies is upon which these forces are impressed. It is obtained from the hypothesis that the tubes of force are physical entities which react against a change of their density. There is nothing in Coulomb's law which suggests this hypothesis and there cannot be, because this law suggests nothing concerning the velocity or the mechanism of transmission of force between electrical charges, whereas a reacting tube of force was suggested to Faraday and to Maxwell by the intuition that electrical actions are transmitted through the tubes of force with a finite and definite velocity which depends upon the dynamical properties, that is, the reactions of the tubes. The tubes of force attached to electrical charges or otherwise generated are, according to this hypothesis, the transmitting mechanism reacting in every one of its elements by reactions which in the case of the vacuum and of ideal dielectrics are identical in form with the elastic reactions of an ideal elastic body. This view of the field of electrical force is one of the foundation pillars of the Faraday-Maxwell electromagnetic theory. I shall next describe briefly the second foundation pillar of this theory.

What has been said above about our knowledge of electrical phenomena is also true of our knowledge of magnetic phenomena. It started its career as a science when Coulomb's measurements succeeded in formulating a law of force between magnetic charges. Since this law is identical in form with that for elec-

3. The term "tubes" is preferable here to "lines" because it brings out clearly the three-dimensional character of these structures.

trical charges, and since the presence of material bodies affects a magnetic field as the presence of material insulators affects an electrical field it is obvious that the Faraday-Maxwell intuitive philosophy leads here to the same results as in the case of electrical fields of force. Coulomb's law can, therefore, be replaced by a law which is identical in form with the law formulated above for electrical fields. It is as follows: *When the field of magnetic force is in equilibrium the external magnetic actions and the internal reactions of the magnetic tubes of force are equal and opposite to each other at every point of space.* Description and hypothesis serve here the same object as in the case of the electric fields, namely, to point out that the magnetic tubes of force are the transmitting mechanism of the magnetic force and that the quantitative relation between the forces impressed upon the tubes and their reactions is one of the determining factors of the mode of propagation.

It is obvious that so far I have been endeavoring to show that Faraday's and Maxwell's views paved the way to the formulation of new concepts, the concepts of electrical and magnetic actions and reactions, which like ordinary material actions and reactions obey Newton's third law. These endeavors will be continued in that which follows.

The law of equality between electrical and magnetic actions and their respective reactions in fields which are in static equilibrium can, obviously, tell nothing definite about the velocity of propagation. Reactions brought into play when this equilibrium is disturbed must be considered. Do they exist, and if so, do they show that the velocity of propagation of electrical force is the same as, or different from, that of the magnetic force? The electrical science prior to Oersted's and Faraday's discoveries could not have answered this question. These discoveries supplied the necessary knowledge. Broadly stated, they revealed the following new truth: Oersted discovered that electrical charges moving through conductors produce magnetic tubes of force which are interlinked with the conductors; Faraday discovered that magnetic charges and their tubes of force produce by their motion or variation electrical forces in conducting circuits which are interlinked with these tubes. This description of the discoveries intentionally emphasizes two facts, namely, that Oersted made his discovery while experimenting with conduction currents, and that Faraday explored the electrical field in conducting wires which are interlinked with the magnetic tubes of force only. The laws resulting from these experiments, namely, Ampére's law and Faraday's law, were necessarily limited to the conditions of the experiments which led to their formulation. Neither one nor the other were sufficiently general to give direct information concerning the unknown reactions associated with the variable electric and magnetic tubes of force at any point of a dielectric. Oersted's and Faraday's experiments did not detect them, nor was it obvious how to detect them experimentally. New hypotheses were needed and Maxwell was the first to formulate them; they were as follows: First, a variation of the flux, that is, the total number of electrical tubes of force through any area, is equivalent to the motion of electrical charges through that area; in other words, the so-called displacement current produces according to Maxwell the same magnetic effect as the conduction or convection current; secondly, the variation of the flux of the tubes of magnetic force through any area produces an electromotive force around the boundary curve of this area which is independent of the material through which this boundary curve passes. These two hypotheses extended the meaning of the Ampère and of the Faraday law and gave them that symmetry which is expressed in the following statements:

The rate of variation of the electric flux through any area is equal to the magnetomotive force in the circuit which forms the boundary curve of that area.

The rate of variation of the magnetic flux through any area is equal to the electromotive force in the circuit which forms the boundary curve of that area.

The first statement represents Maxwell's generalization of Ampère's law, and the second that of Faraday's law. Mathematical physicists call them Maxwell's field equations. This name does not convey clearly their physical meaning, nor does it express fully their historical significance. Prior to the time of Oersted and Faraday there were only a few rather feeble processes of generating and impressing upon material bodies electric and magnetic forces: Frictional machines, galvanic cells, action of permanent magnets, etc. . . . Ampère's and Faraday's generalized laws describe new processes of generating and impressing magnetic and electric forces *upon any part of space.* They might be called Maxwell's laws of electrodynamic generation, or briefly *Maxwell's laws,* the rest of the proposed title being understood. These laws give the total sum of the electric and magnetic forces impressed by those processes upon any circuit; the energy principle tells us that this sum is equal to the sum of the electric and the respective magnetic reactions in the circuit. The parcelling out of the total impressed forces thus generated among the volume elements of the circuit and the character of the reactions of each volume element must be determined by the character of each problem and by the physical properties of each volume element of the circuit. Circuits in ideal isotropic dielectrics present the simplest illustration of the general procedure, and this was the subject which Maxwell considered first. In this case the reaction per unit cross-section and unit length of the circuit is, as already pointed out, equal to the ratio of the flux density to the specific inductive capacity, or permeability, respectively, and this reaction must be equal to the force generated by the variable fluxes and impressed per unit length of the circuit. This leads to a reciprocal relation between the electric

and magnetic reactions in variable fields which in an isotropic dielectric exhibits a process of propagation identical in form with that obtained by Newtonian dynamics for the actions and reactions in an isotropic, incompressible, elastic medium. Maxwell's greatest achievement is, in my opinion, his introduction into the electrical science of new concepts, electric and magnetic actions and reactions, which are subject to the same laws as the corresponding concepts in Newtonian dynamics. But it should be observed here that Maxwell's success was due to Faraday's suggestive description of the electric and magnetic fields in terms of tubes of force and to the intuition which created the epoch-making hypotheses endowing these tubes with dynamical attributes formerly belonging to material substances only. These hypotheses demanded experimental verification; Hertz seized the opportunity and furnished the epoch-making demonstration of the correctness of Maxwell's hypotheses.

The propagation of force through an ideal elastic solid makes the velocity of propagation depend upon two constants only, the density and the elastic constant. The first determines the inertia reaction and the second the elastic reaction per unit volume of the solid. Similarly in the propagation of the electric force through the electric and magnetic tubes of force in an ideal dielectric the velocity of propagation depends upon two constants only, the specific inductive capacity of the tubes and their magnetic permeability. One determines the reaction of the electrical tubes of force and the other the reaction of the magnetic tubes. These reaction constants determine the velocity of propagation through the electric and magnetic tubes in the same manner as density and elastic constants determine the velocity of propagation through ideal elastic bodies. The question arises, as to which of the two reaction constants of Faraday's tubes corresponds to the density and which to the elastic constant of material bodies. In other words, which of the two constants is characteristic of the inertia reaction of the tubes?

The generalized laws of Ampère and of Faraday, which I call the Maxwell laws, suggest a permissible answer to this question. They indicate a scheme which demands one primary or fundamental flux only, the electric flux. A variation or velocity of motion of the electric flux generates, according to the first Maxwell law, magnetic forces and corresponding magnetic fluxes which in an isotropic dielectric are proportional to the impressed magnetic forces, the factor of proportionality being the magnetic permeability of the tubes of the magnetic field. If, therefore, we consider the magnetic flux of the field, thus generated, as the momentum of the varying or moving electric flux, since it is proportional to its rate of variation or velocity of motion, then the electrical field generated, according to the second Maxwell law, by the variation of the magnetic flux will be due to the change of this momentum. According to this scheme the permeability constant in the electromagnetic theory would correspond to density in the theory of propagation through elastic solids.

Electron physics supports this scheme. It traces the origin of all magnetic forces of magnets to the orbital motions of electrons. This reminds us of the old Ampèrean conception. Magnetic tubes of force associated with so-called permanent magnets are, according to electron physics, the result of the motion of electric tubes of force attached to electrons. Maxwell always associated with magnetic tubes of force the momentum of some electric motions; what Faraday called the electrotonic state, he called the electro-kinetic momentum of a circuit, that is, the magnetic flux interlinked with the circuit. The reactions of varying magnetic tubes of force are, therefore, inertia reactions, and their reaction constant, the permeability, should, as already pointed out, be considered as corresponding to the density of elastic solids, whereas the reciprocal of their specific inductive capacity corresponds to the elastic constant. Faraday's tubes of force in free space have, in electromagnetic units, a permeability equal to unity and, measured in the same system of units, an exceedingly small specific inductive capacity. They behave, therefore, like incompressible elastic bodies of moderate density but of very high elastic constant for shearing strains. It is equal to 9×10^{20}. Hence the great velocity of propagation of electromagnetic disturbances through tubes of force in free space, as experimentally verified by Hertz.

Electrical propagation through ideal dielectrics, including the vacuum, demands, according to the above picture, nothing more than Faraday tubes of electric force (which I call here *primary flux*) capable of two distinct reactions, one an electrical reaction and the other a magnetic, that is an inertia, reaction. The tubes react like a material medium of reasonable density but of most extraordinary stiffness. But neither this similarity to material bodies nor anything else in our present knowledge of electrical phenomena justifies the hypothesis that they consist of a substance which has qualities of ordinary matter in bulk. One cannot resist the temptation of asking the question: What are these tubes made of? I venture, therefore, to offer the following pardonable suggestion.

Our ideas of these tubes are associated with our concepts of electrical charges which are the terminals of the tubes when they have a terminal. In this we follow in the footsteps of Faraday. It is not an unreasonable hypothesis to assume that they are made of the same fundamental substance of which the electrical charges are made. The name "electricity" may, therefore, be reserved for that substance, whatever it may be, so that we may say: The medium which transmits electrical disturbances is "electricity," meaning thereby the electrical tubes of force. Light is an electrical disturbance and it is, according to this view, transmitted by electricity. The concept suggested by the word "electricity" is much more definite than that suggested by the words "lumeniferous ether," because we associate

with electricity two perfectly well known and experimentally determinable reaction constants, that is, the reaction constants of the primary flux of force at rest and in motion. These are the only attributes that we can dynamically predicate of a material substance, hence the concept "electricity" is dynamically just as definite as the concept "material substance"; the concept "ether" is not.

Perhaps I have dwelt too much upon that part of the electromagnetic theory which is a little outside of the daily problems of the electrical engineer. Some people think that it is entirely outside of the theory which underlies electrical engineering problems. Permit me to show you, as briefly as I can, that this is not so, and that the same form of laws and the same dynamical methods apply to electrical engineering problems as to the problems discussed above. Electrical engineering problems deal with actions and reactions in electrical and magnetic circuits and so does the general electromagnetic theory. I have pointed out how starting with Coulomb's law a more general law was formulated for the field of force due to electrical or to magnetic charges at rest, the law of equality of actions and reaction in every volume element of the field in static equilibrium. The validity of this law was maintained for the dynamical equilibrium of variable fields when Ampère's and Faraday's laws were formulated by Maxwell in their most general form. The principle of conservation of energy demands that this law be always true irrespective of the physical character of the circuit or of the process of generating the impressed forces. This furnishes then the most fundamental basis in theoretical electrical engineering. It may be stated as follows:

In every circuit or part of a circuit the algebraic sum of electrical reactions is equal to the algebraic sum of the impressed electrical actions.

Omit the words "electrical" from this statement and you have the most fundamental law in Newton's dynamics, showing that "electricity" obeys the same fundamental law which ponderable matter obeys.

Take for an illustration an electrical circuit in which we have a constant electromotive force, generated by a voltaic cell, and a constant current flowing through a conducting wire. Consider any two points on the wire. Heat is generated in the wire between these two points and, therefore, there must be an electrical reaction in the wire between these two points. Heat is the result of the work done against this reaction by the impressed electrical force transmitted by the battery. This reaction may be called a *resistance reaction,* whereas the impressed action is the difference in potential between these two points. The law of equality of action and reaction says: The resistance reaction is equal to the difference of potential. This relation is independent of the so-called "Ohm's Law." When, however, the wire is maintained at constant temperature its resistance reaction is found by experiment to be proportional to the current; this empirically established characteristic of most metal wires is called Ohm's law. It really is not a law any more than Joule's rule for the rate of heat generation by a current flowing through a metal wire. Both are accurate empirical descriptions of a physical characteristic of most metal wires. It is occasionally stated with some show of disappointment that the flow of current through a gas does not obey Ohm's law, which really means that the resistance reaction is not proportional to the current, and that it cannot be described as simply as the resistance reaction of a metal wire. That a conducting gas should react differently from a conducting metal wire should not surprise anybody; but it seems that it does.

Consider, as another simple illustration, a toroidal magnetic circuit consisting of several different radial sections of different kinds of steel separated from each other by small air gaps and magnetized by a current flowing through turns of wire wound uniformly around the toroid. The total magnetomotive force generated by the current is given by Ampère's law. Each part of the magnetic circuit receives its definite share of the total magnetomotive force; this share is the magnetizing force impressed upon that part of the circuit. In each part of magnetic circuit the impressed magnetizing force is equal to the magnetic reaction of that part, so that according to the fundamental law the sum of the magnetic reactions is equal to the total impressed magnetic actions, which is the magnetomotive force. This is the fundamental law, whereas the usual method of calculating, roughly, the magnetic flux from impressed magnetizing forces and reluctances by making use of a new kind of Ohm's law for the magnetic circuit is, in my opinion, a misleading use of the word law. This spurious Ohm's law is abandoned, of course, as soon as we attempt to devise an experimental method for measuring hysteresis losses during a complete cycle of magnetization, but we do not abandon the dynamical law that in every part of the magnetic circuit the magnetizing force is equal to the magnetic reaction. On the contrary, we could not without it interpret dynamically the hysteresis losses during cyclic magnetizations.

When in a network of linear conductors alternating-current generators are located at various points of the network, the current distribution in the network can be calculated by setting up equations for each circuit which state the fundamental dynamical law that in each circuit the algebraic sum of electrical reactions is equal to the algebraic sum of impressed electromotive forces, generated by the alternators. To call these equations mathematical expressions of a Kirchhoff law, as some do, is unpardonable abuse of language. Kirchhoff gave the *rule* that for any circuit in a network of metalic wire conductors in which there are sources of constant electromotive force the algebraic sum of the electromotive forces is equal to the algebraic sum of the

products of current and Ohmic resistance, but he never suspected that this is a special case of the fundamental dynamical law given above.

It is true that in 1858 Kirchhoff, in his analysis of electrical propagation along an overhead telegraph wire, stated correctly the relation between the electrical reactions at any element of the wire, and in this statement he was guided by Thomson's discussion of electrical propagation over a submarine cable. But neither Thomson nor Kirchhoff were aware of the general law stated above. Maxwell's Electromagnetic Theory had not yet been published, and prior to that publication the general law implicitly contained in this theory, and which is today the foundation of electrical engineering, could not be formulated.

The several simple examples, cited above, suffice to illustrate clearly that electrical engineering problems on their pruely scientific side are formulated in the same way as the problems in the general electromagnetic theory. Their solutions are obtained by the application of the same form of the fundamental laws employing the same methods of reasoning and the same terminology which Newton had formulated when he created the science of dynamics. The possibility of describing electrical phenomena in terms of Newton's concepts and language is one of the greatest achievements of Faraday and Maxwell. Law, description, and hypothesis were never employed with greater effect than by the genius of these great prophets of the electrical science.

Corona Investigation on an Artificial Line

BY MURRAY F. GARDNER*

Associate A. I. E. E.

Synopsis—Accompanying corona on a transmission line, there has been found, in several cases, an appreciable increase in the line charging current over that indicated by the usual formula. This has been taken to indicate an increased line capacitance resulting from the presence of the corona envelope about the conductors, and has, for this reason, come to be described as the extra-capacity effect of corona. This explanation, by an envelope, however, has not been entirely satisfactory, and the question has arisen as to whether the current increase could not have been equally as well attributed to the current and voltage harmonics which the corona introduces.

The paper describes an investigation made of this extra-capacity effect on an artificial transmission line using artificial corona. In avoiding, by means of this method, the glow discharge of real corona, all envelope effects were eliminated. The operation of the artificial corona is described, and the results given of the tests which were made in checking its characteristics against those of real corona.

By means of the artificial corona it is shown that it is possible to obtain the extra-capacity effect of corona without having present an ionized envelope. The explanation is offered that at least the larger portion of this effect found on transmission lines under corona conditions is apparent only; that it is a result of the approximate method by which the line capacitance is calculated, and the increased admittance which the line offers to currents of harmonic frequencies.

The effect of corona leakage in altering potential rise on an open line is shown by representative voltage distribution curves taken on an artificial line with and without the corona leaks operating. From a comparison of these curves it appears that the leakage of corona plays a predominant part in the establishment of the resultant voltage, the harmonics caused by the corona in no case producing unusual resonance effects or extra-potential rises. This is important largely for the indication it gives that the present methods of predetermining voltage distribution on open lines for corona conditions are accurate within the limits of engineering accuracy.

Qualitative results are given showing the effectiveness of corona leakage in reducing traveling waves such as result from switching operations. Two oscillograms of the same transient are shown, one taken with the corona leaks operating and the other without. The much shorter duration of the transient in the former case is evidence of the corona's effectiveness in absorbing the energy of the disturbance.

INTRODUCTION

UNDER ordinary conditions air is a good insulator, but it loses this quality when subjected to an excessive potential gradient, such as occurs near the surface of the conductors of a transmission line when the voltage between lines is increased above a limiting value. In this region of maximum stress, ionization takes place and there is formed about each conductor an envelope of semi-conducting and luminous air, called corona. This envelope is believed to relieve the concentration of stress by increasing the effective diameter of the conductors.

There is a minimum corona-forming voltage, e_0, for every line, dependent upon the configuration of its conductors and the atmospheric conditions under which it operates. With an alternating voltage, the maximum value must exceed this critical voltage before corona forms. If much in excess, the corona starts at e_0 on the increasing portion of each half-voltage wave, and continues until a slightly lower value is reached on the decreasing portion. Corona under these conditions is pulsating, its frequency being double that of the voltage. This pulsation causes a cyclic change in line admittance which introduces harmonics, particularly the third.[1]

Accompanying corona, there is a power loss which increases with the square of the excess voltage over the critical value. This is expressed by the formula[2]

$$p = c^2 (e - e_0)^2$$

where p is in watts, c is a constant, e is the applied voltage, and e_0 is the disruptive critical value for the line.

2. F. W. Peek, Jr., "Dielectric Phenomena in High-Voltage Engineering", 1920, p. 122.

This quadratic law holds except in the neighborhood of e_0, where varied results are obtained due to surface irregularities on the conductors.

Due to corona loss it has been customary to operate lines well below their corona-forming voltage. But with the large blocks of power now transmitted, it becomes feasible, with certain systems, to raise the operating voltage practically to the corona limit. In seasons of unfavorable weather it is to be expected, therefore, that portions of these systems will operate for considerable periods in a state of corona.

This continual presence of corona, in addition to causing high energy loss, may be a source of serious interference between the transmission line and neighboring communication circuits. The corona introduces an appreciable third harmonic, and this is within the range of audibility in the case of a 60-cycle current. If the power system is three-phase and has its transformers connected in grounded-Y, these triple-frequency currents can flow through the three lines in parallel, combine in phase in the neutral, and complete their circuit through the ground. This induces troublesome voltage disturbances in paralleling telephone and telegraph lines. If the power system does not have a grounded neutral, it is impossible for the third-harmonic currents to flow. To compensate for this, a third-harmonic voltage appears between each line and neutral.[1] These voltages, being in phase, cause the whole system to pulsate with a triple frequency to ground. This pulsation induces a voltage between lines and ground in the paralleling circuit which even transposition will not eliminate. It appears, therefore, that interference due to corona harmonics presents a serious problem in any extensive operation above the corona-forming voltage.

On the other hand, the presence or ready formation of corona may be of some advantage. It may assist in damping high-voltage transients.[3] When operating near the corona limit, the rapidly increasing energy loss for slight rises in potential above normal is likely to be of considerable value in absorbing and quickly attenuating these disturbances. Corona's real effectiveness in this respect, however, has not been definitely determined.

The leakage effect of corona may also be of assistance in keeping down the magnitude of potential rise at the open end of a long line should the line accidentally become open-circuited. This reducing effect would be desirable, as the rise subjects the insulators to high potential strains, and causes the line to draw an excessive charging current from the connected generators.

A further interesting feature of corona is the discrepancy found between the measured charging current for a line and that indicated by the usual formula, when voltages are used which are above the critical corona value.[4] As the line potential is raised from low values up to e_0, the charging current increases proportionately. Slightly above, as corona forms, the current diverges from the linear relation, and for higher voltages, rises much more than proportionately. Since this is the same result as would be obtained were the line capacitance to increase above normal at these high voltages, the divergence has come to be described as the extra-capacity effect due to corona.

There are several explanations of this non-linear increase of current. Usually it is explained by assuming the line capacitance to be increased due to a cyclic change in effective conductor diameter caused by the corona. To account for the total test charging current in this way, however, requires in some cases an effective conductor of from fifty to eighty times normal diameter.

This explanation is also open to question due to the fact that it assumes that, were the capacitance to remain normal under corona conditions, the charging current would continue to rise linearly with the voltage. It is believed that the current might rise above the linear relation even with a normal capacitance, because of the corona harmonics. From this standpoint, it would seem more likely that the increase is the result:

1. Of the very approximate method by which the capacitance current is calculated.

2. Of the increase in admittance which the line, like any other circuit of relatively high capacitance, offers to currents of harmonic frequencies.

In these two explanations there is involved no action of the corona envelope, the current increase being considered the result solely of harmonics.

Purpose

The purpose of this paper is to present the results of an investigation carried on in the Research Division of the Electrical Engineering Department, Massachusetts Institute of Technology, aimed at the representation of corona effects on artificial lines. It describes the artificial corona which was developed, and gives the results of tests in which it was used. The latter tests were for the purpose of: First, obtaining experimental evidence in support of the "harmonic" explanations for the increased charging current which accompanies corona; second, determining the effect of corona in altering voltage distribution; and third, investigating its effectiveness in reducing traveling waves in the system.

Development of an Artificial Corona

As evidence was sought to show that the increased charging current is the result of harmonics rather than of the corona envelope, it was necessary to have a check upon the envelope effect. This being practically impossible with real corona, the envelope was eliminated

from consideration by simulating the corona effects artificially on an artificial line.

The artificial corona consisted of a representation of the cyclic change in line leakage peculiar to corona. The leakage variation was obtained by the use of three-electrode vacuum tubes, the current characteristics of

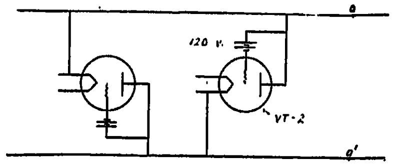

FIG. 1—CONNECTIONS OF ARTIFICIAL CORONA LEAK

which are in many respects similar to those of ionized air. As the tubes pass current only in one direction, two were necessary for one complete leak—one to operate on the positive half of the voltage cycle and the other on the negative half. Fig. 1 shows the interconnection used.

The operation of the leak depended upon the non-linear characteristics of the tubes. The filament of the first tube and the grid and plate of the second connected to one line wire, while the filament of the second and the grid and plate of the first connected to the other line wire. The breakdown voltage, that is, the e_0 of the leak, was governed by a bias potential of approximately 120 volts in each grid circuit. This, with the type of tube used (*V T*-2), kept the grid negative and the tube inactive until 115 volts, instantaneous between line wires, was reached on the ascending portion of the wave. With a plate potential of 115 volts and the grid 5 volts negative, conditions were favorable for the passage between line wires of a small plate current through one tube. As the maximum rose above 115 volts, the grid of this tube became less negative and finally positive, while its plate potential steadily

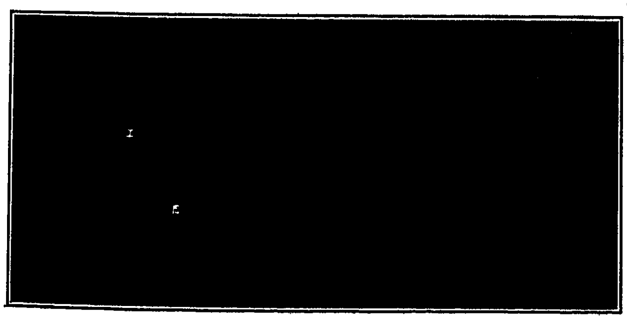

FIG. 2—DISCONTINUOUS LEAKAGE CURRENT GIVEN BY THE ARTIFICIAL CORONA LEAK

increased. This resulted in a rapidly increasing leakage current up to the crest of the voltage; beyond, on the descending portion of the wave, the action was reversed. The leak was then inactive until the second tube repeated the cycle under the negative voltage loop.

The leak may be likened to a two-way valve, in that it permitted leakage only for the intervals during which the instantaneous values of the voltage wave exceeded its breakdown value, e_0. It gave a small, discontinuous leakage current, Fig. 2, which was zero at all times except under the crests of the voltage wave. The shape and amount of this current could be controlled by adjustment of filament temperature and bias potential. By increasing the latter, the breakdown voltage was increased, and the leakage reduced. If the breakdown

FIG. 3—CURRENT OBTAINED WITH ARTIFICIAL CORONA LEAK AND CONDENSER IN PARALLEL

voltage had been established, the amount of the leakage could be controlled by the filament temperature. As used in the following tests the r. m. s. critical voltage, e_0, for the leaks was approximately 75 to 80 volts, representing $\frac{115}{\sqrt{2}}$ volts.

By shunting the terminals of the leak with a small

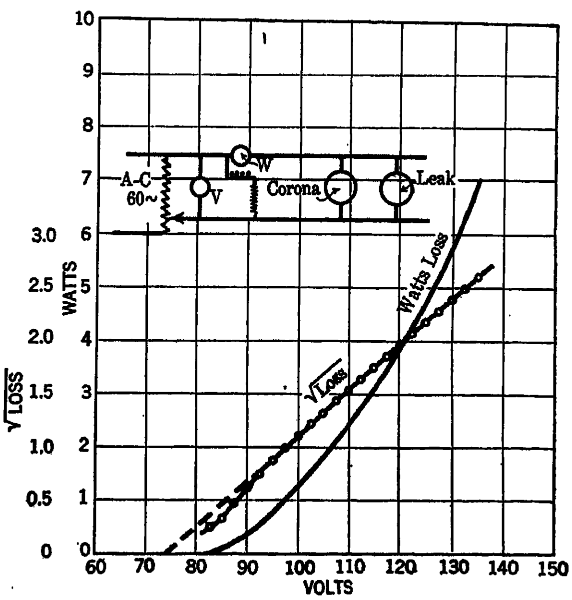

FIG. 4—CURVE SHOWING THAT THE ARTIFICIAL CORONA LEAK SATISFIES THE QUADRATIC LAW OF CORONA LOSS

paper condenser at $a\ a'$ in Fig. 1, the distorted current shown in Fig. 3 was obtained. As a voltage greater than e_0 was applied, there was a leakage current in addition to a charging current, the leakage current causing a hump on the latter slightly in advance of each voltage crest. The smaller irregularities in the current were due to tooth harmonics in the voltage wave.

In later tests these were eliminated by the use of filters.

That the leakage current of the artificial corona was similar to that of real corona may be observed by comparing Figs. 2 and 3 with the wave forms obtained of the latter by Whitehead[5] and by Bennett.[6] In both of these cases, the real corona was formed on a rod within a concentric cylinder. The oscillograms of Bennett show the distortion caused by corona of the rod-and-cylinder capacitance current when the applied voltage exceeded the critical corona-forming value for the apparatus. The corona introduced a hump into the charging-current wave just in advance of each voltage crest. In the duplication of this, with the artificial

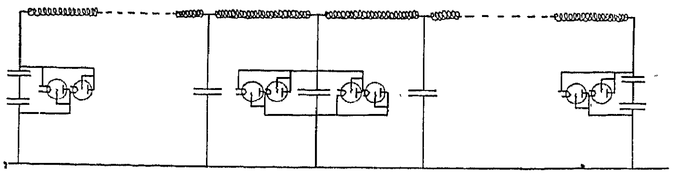

FIG. 5—CONNECTION OF CORONA LEAKS TO THE ARTIFICIAL LINE

corona, the capacity effect of the rod and cylinder was supplied by the small fixed condenser shunting the leak terminals. The wave forms reported by Whitehead were obtained by a separation of the total current, as found by Bennett, into two parts—a charging current and a corona current. For this the current wave was taken, first below and then above the critical voltage, the difference between the two giving the wave form of the corona current. This latter was pulsating. Its

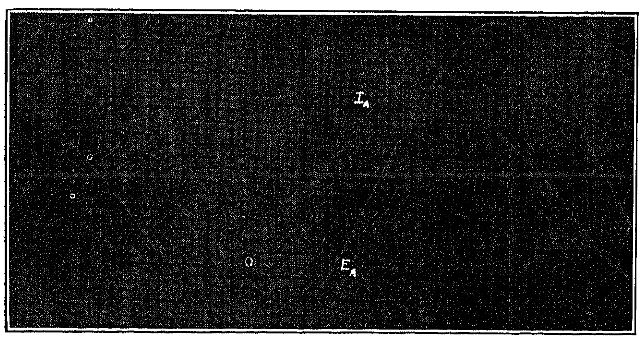

FIG. 6—CHARGING CURRENT FOR AN ARTIFICIAL LINE HAVING ARTIFICIAL CORONA LEAKS

humps were asymmetrical, but they attained their maximums approximately under the crests of the voltage.

The conformance of the artificial corona to the quadratic law of corona loss is shown by the typical power-loss curve given by a single leak (Fig. 4). The test for this type of curve consists of a plot of square root of the power against volts, the points of which should lie on a straight line. The leakage curve satisfied this requirement, as shown. The straight-line plot may be compared favorably with similar plots given by Peek[7] It is interesting to recall, in this connection, that the deviation from the theoretical curve in the region of e_0 is also a characteristic of real corona.

The artificial line to which the corona leaks were attached represented a single-phase line having 500,000-cir. mil conductors, spaced 9 ft. between centers.[8] One leak was placed at each end and two leaks in parallel at the middle. This was in accordance with the pi-construction of the line, and gave twice the leakage at the middle as at the ends. See Fig. 5. The critical voltage, e_0, for the line was established at 81 volts.

Using a 420-mile length of open line, oscillograms were taken of voltage and charging current at the generator

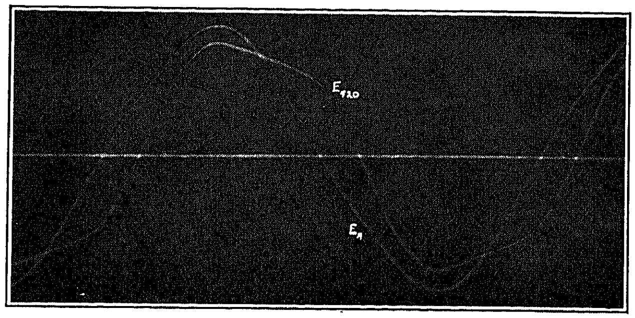

FIG. 7—VOLTAGE WAVE FORMS AT THE TWO ENDS OF A 420-MILE LINE WITH CORONA LEAKS OPERATING

end, both with and without the leaks operating. When they were attached, but inoperative, (filament currents zero), the current and voltage were normal sine waves. When placed in operation, they caused the distortion shown in Fig. 6. Analysis of the wave forms of the latter showed the voltage to have a three per cent third harmonic, and the current to have a nine per cent third harmonic, three per cent fifth harmonic, and one and three-tenths per cent seventh harmonic. These compare favorably with the voltage and corona-plus-capacity-current wave forms at the generator end of a real transmission line under corona conditions, as given by Peek.[9]

By these preliminary experiments the characteristics of the artificial corona were checked against those of real corona. It was shown that the leakage current was of approximately correct wave form, and that the power loss varied with the voltage in agreement with the quadratic law. Further, when operating on the artificial line, the distortion produced in the voltage and

current was similar to that found with real corona on a real line.

Distortion of Voltage

Oscillograms were now taken of voltage wave forms at points out along an open line. The use of a vacuum-tube repeater[10] made it possible to attach the oscillograph to the unloaded line without disturbing voltage conditions. When the leaks were inoperative there was no distortion at any point on the line. But when they were placed in operation, they produced the distortion shown in Fig. 7. Only the two end voltages are given, as they represent the extreme conditions. Analysis of all the waves of the series was made, however, and it was found that the distortion was progressive. It consisted almost entirely of a third harmonic, the magnitude of which increased steadily from four to fourteen per cent between generator and open end.

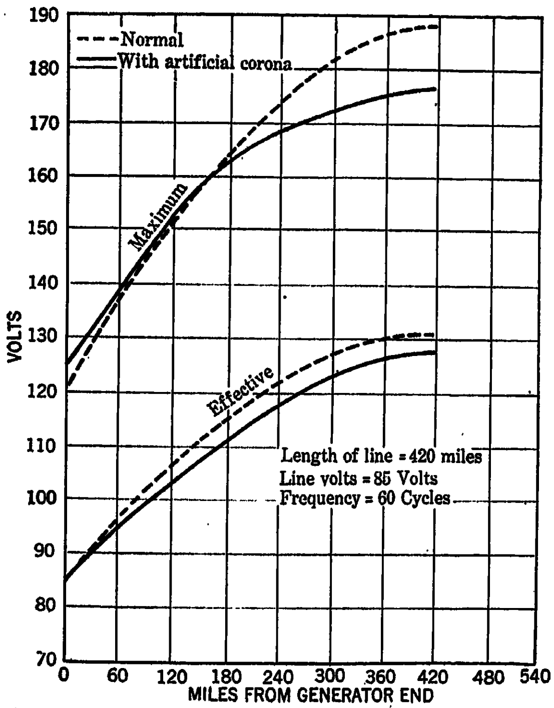

Fig. 8—Crest and R. M. S. Voltage Distribution on 420-Mile Line, with and without the Artificial Corona

Using a vacuum-tube, crest-reading voltmeter (also arranged to take negligible power), the maximum voltage values at positions along the line were found in similar manner. Under corona conditions the crest value was increased near the generator end, but decreased near the free end, as shown in Fig. 8.

This progressive increase in voltage distortion is due to the difference in resonance conditions for the fundamental, and for the various harmonics. The latter, as a result, become a larger percentage of the resultant voltage at the distant points.

This distortion of the voltage along a single-phase line is of interest, since it occurred under conditions which provided a circuit for third-harmonic currents. A three-phase line with grounded neutral is equivalent to three such single-phase lines in parallel. The results indicate, therefore, that even with a grounded-neutral system there can be a distortion of voltage between each line and ground. It is of interest also in connection with the explanation given later of the charging current which is found under corona conditions.

Any alteration in maximum voltage values, such as was found, would have an appreciable effect upon the distribution of corona loss, increasing it at the near end and decreasing it at the far end of the line.

Effect of Corona Leakage on Voltage Distribution

An excessive potential rise on an open line under corona conditions has been reported.[4] This has raised questions regarding the effect of corona in altering voltage distribution in cases of open circuit, and the possibilities of serious resonant voltages at triple frequencies.

These points were investigated with the artificial corona. Voltage distribution curves were taken with an electrostatic voltmeter over a wide range of line lengths and voltages, with and without the corona leaks operating. The curves shown in Fig. 8 are typical of the alteration in distribution found in every case. To this, even a 240-mile line proved no exception. This is important as this line represented approximately a quarter-wave length for the third harmonic of sixty cycles—a condition which would be most favorable for the formation of high-resonant voltages by the corona if resonance effects of the harmonics should prove to be present.

In these tests it was found that the normal voltage distribution, that is, for no corona leakage, held also for corona conditions unless the applied voltage was excessively high or the length of line extreme. With a long line and an applied voltage near the critical value, the distribution was appreciably lowered. It appears, therefore, that in the case of distributions on long lines the reducing effect of corona as a leakage will largely overbalance any tendencies toward high voltage resonance due to the harmonics it may introduce.

In making voltage distribution computations for high-voltage lines where corona must be considered, it has been customary to represent the probable corona loss by an equivalent ohmic leakance. In this, the assumption has been made that corona would tend as a leakage to reduce the rise of potential should the line accidentally become open-circuited. The above results appear to substantiate this assumption. Further, it was possible in the case of each of the tests on the artificial line to calculate a distribution which would agree within the limits of engineering accuracy with

10. F. S. Dellenbaugh, Jr., "*Artificial Transmission Lines with Distributed Constants*," Journ. A. I. E. E., Dec. 1923, p. 1293.

4. loc. cit.

the distribution obtained by test. For this the usual hyperbolic formulas were employed, using a leakance, g, obtained from the division of measured loss by the average of the squares of the end voltages.

For all these tests it was possible to check the adequacy of the corona representation. The critical corona voltage of the single-phase power line, which the artificial line represents,* is approximately 95.2 kv. to neutral, assumptions being made as to atmospheric conditions and state of conductor surface.[11] As this corona-forming voltage was represented on the artificial line by 81 volts, the ratio between corresponding line

FIG. 9—CURRENT TRANSIENT ON OPEN LINE WITHOUT CORONA SWITCH CLOSED 115 DEG. AFTER VOLTAGE PASSED THROUGH ZERO

voltages was $\frac{81}{95{,}200}$. It was thus possible to check the corona representation, as the corresponding losses on the artificial line and on the real line were to be to each other as the square of this voltage ratio. In all cases the loss measured was found to be within 10 per cent of the loss which was calculated for the condition by this method.

EFFECTIVENESS OF CORONA IN DAMPING TRANSIENTS

Tests were also made to show the possible effectiveness of corona in attenuating traveling waves, such as result from switching operations in the system. For this a single-phase artificial line with distributed constants was used. It represented 331 miles of No. 00 solid copper conductors having 8 ft. 9 in. spacing.[10]
A synchronous switch closed the circuit between generator and line at any desired point on the voltage wave. Two oscillograms for each point of switch-closing were taken—one to show the transient under normal conditions, and the other the same transient with corona present. Their difference represented the modification resulting from the corona leakage.

In Figs. 9 and 10 are given typical transients for the two cases. They show the generator voltage and the current entering the open line when the switch was closed on the descending portion of the voltage wave. In the first, without corona, the deviation from the sinusoidal state is apparent for approximately two cycles, and six reflections are distinguishable. In the second, taken with corona present, the steady-state condition was reached in half a cycle. In this latter, the normal distortion of the current due to the corona should not be confused with the transient.

Although these last results are only qualitative, they support the general belief that corona, as a leakage occurring with excessive voltage, acts to suppress abnormal voltage disturbances. In functioning as a safety valve, it serves to dissipate the excess energy of the traveling waves and reduce them rapidly to the steady-state condition.

EFFECT OF HARMONICS ON APPARENT CAPACITANCE

In corona loss tests on transmission lines, readings are taken of current, voltage, and power. From the ratio of watts to volt-amperes the power factor is calculated, and thereby the line current resolved into two components—one in phase with the voltage, and the other at right angles and leading. The latter, (considered the charging current for the line capacitance) increases linearly with the voltage up to the point of corona formation; beyond, it bends rapidly upward. Curves showing this are given by Lewis[4] and Peek. The variation from the linear relation above the critical voltage is generally attributed to the presence of the corona envelope increasing the line capacitance.

This feature of corona was investigated on the artificial line. Corona loss tests were made, and essentially the same procedure followed in measurement and calculation as outlined above. For each voltage the value of line capacitance corresponding to the quadrature current was computed. The results, given in

FIG. 10—CURRENT TRANSIENT AS SHOWN IN FIG. 9, BUT WITH CORONA

graph form in Fig. 11, show in the upper part the variation of volt-amperes, net watts of corona loss, and power factor with applied voltage. In the lower part are given the total current, corona current, charging current, and the apparent capacitance. There is an interesting similarity between these and the characteristic curves of real corona.

The true capacitance of the 189 miles of artificial line was 1.445 microfarads. The capacitance calculated to agree with the test charging current at a voltage 40 per cent above the critical value was 1.51 microfarads. Thus with only the leakage effect of corona represented,

*See page 816.
11. F. W. Peek, Jr., "Dielectric Phenomena in High-Voltage Engineering," 1920, p. 203.
10. loc. cit.

the capacitance of the line was apparently increased 4.6 per cent, and this with no actual change taking place in the fixed condensers which supplied it. In this connection, Lewis reports an increase of 32 per cent, found when the voltage was 70 per cent above the critical value. Although small in comparison with this, the increase which was obtained on the artificial line showed plainly that an ionized envelope is not an essential to the occurrence of this effect.

It was possible to show in another way that at least much of this capacitance change found on lines is apparent. The above test was repeated, measuring only the loss in a single corona leak shunted by a fixed condenser. The quantities, Fig. 12, were calculated as for

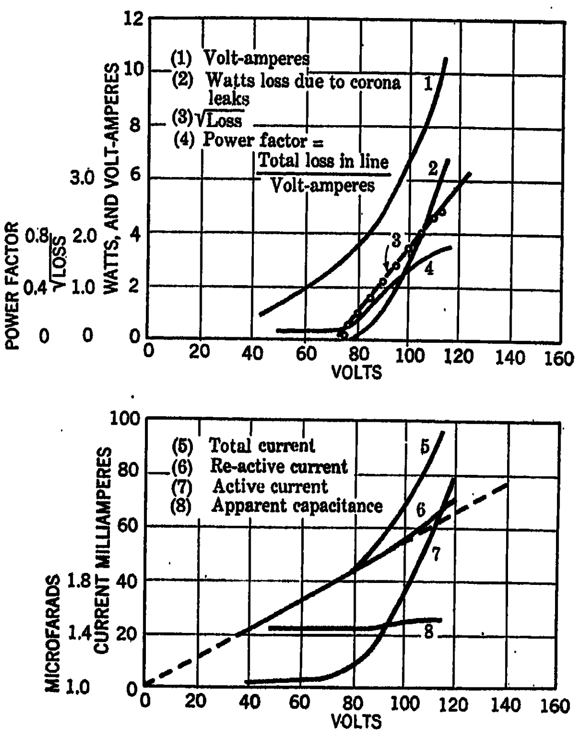

Fig. 11—Characteristic Corona Curves Obtained on an Artificial Line having Artificial Corona, Showing Typical Increase in Line Capacitance

a line. The curves are almost exact duplications in form of those given for real corona. The charging current and apparent capacitance of the condenser were distinctly increased at voltages exceeding the critical value of the leak. The capacitance changed from 1.06 to 1.25 microfarads, which is a 21 per cent increase for a voltage 67 per cent above the critical value. These results were obtained, using a voltage of approximately 100 volts; there was no corona envelope; and the true capacitance of the circuit was known to remain constant, being a fixed condenser.

In both of these tests the increase in charging current was *real*, but the increase in capacitance only *apparent*. This may be explained by the presence of harmonics.

In the transmission line case there was a distinct distortion of the voltage between line and ground out along the line due to the corona harmonics. (Shown in Fig. 7). Being impressed on the normal line capacitance, these harmonic voltages produce large charging currents due to the fact that there is an increased susceptance to currents of harmonic frequencies. The result is that the quadrature, or capacitance component of the line current, is increased more than proportionately to the applied voltage.

Further, as shown in Fig. 6, the current at the generator end of the line under corona conditions was highly distorted in comparison with the voltage at that point. The meters connected there for measuring the current and voltage indicated only the effective values of the

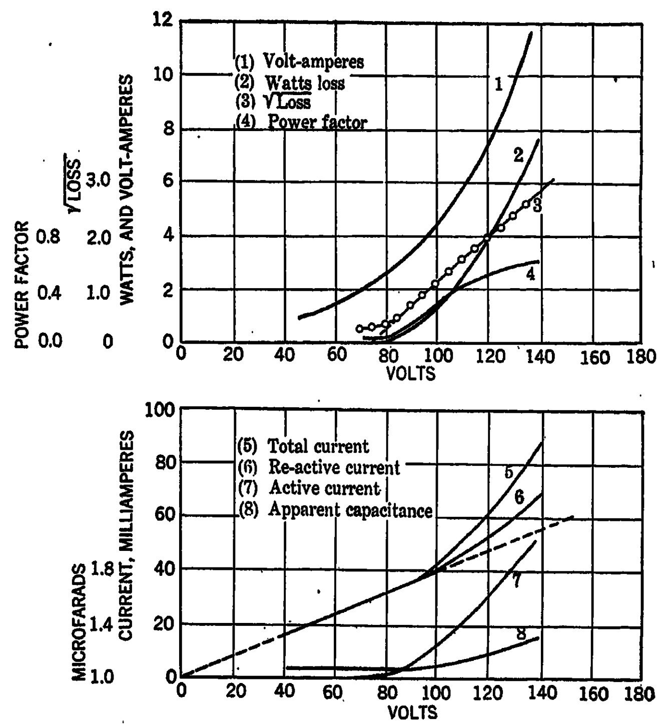

Fig. 12—Characteristic Corona Curves Obtained with an Artificial Corona Leak Shunted by a Fixed Condenser, Showing Apparent Increase of Capacitance

wave forms, and in making the subsequent computations, equivalent sine waves having these values were substituted for the distorted waves.

The error introduced by neglecting the harmonics in making the calculations is brought out by the results of the test on the leak and shunting condenser. In that case the current and voltage wave forms were as shown in Fig. 3; the current only was distorted, the voltage remaining practically sinusoidal. This produced a decrease in the power factor, for the harmonics which existed in the current and not in the voltage contributed nothing to the average power, but did increase the effective value of the current required to produce that power. The result of this is shown by the vector diagram of Fig. 13.

The fundamental I_1 of the current has an energy component I_e in phase with the voltage, V. As the

voltage is sinusoidal, this is the only part of the current that contributes to the power. The harmonics increase the effective value of the total current from I_1 to I, but its energy component must remain the same. Consequently, when an equivalent sine wave is used for I, as is done in making the usual computations, the result is an increased quadrature current I_q, and corresponding apparent capacitance calculated from $C = \frac{I_q}{\omega V}$.

The results of the above tests are evidence that the capacitance change attributed to corona is not at least entirely a phenomenon due to the presence of an envelope. The indications are that it is a direct result of distorted wave forms, and of a method of calculation in which only equivalent sine waves are considered. The "change in capacitance" accompanying corona is a means of describing a particular effect, that is, the upward bend of the charging current, and its explanation therefore is largely a matter of definition. Although capacitance is usually defined as the charge per unit rise of potential, it is not likely that the ions of the corona envelope constitute a charge in the true sense of the word, as probably little of the charge in the envelope can return to the conductor as the voltage drops from its crest value.

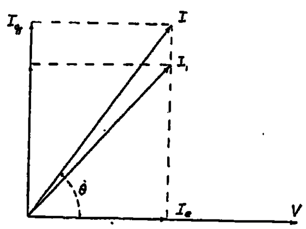

FIG. 13—ILLUSTRATING HOW INCREASE IN CAPACITANCE RESULTS FROM THE SUBSTITUTION OF EQUIVALENT SINE WAVES

The final proof of whether or not there is a real capacitance change may well lie in the actual measurement of a line capacitance both with and without corona present. Tests of this nature have been made at Massachusetts Institute of Technology by M. T. Dow. An exploring wire was placed in the field near one of the conductors of a laboratory span, upon which was formed direct-current corona, and the capacitance between the wire and conductor measured. This is a method laden with experimental difficulties due to the high voltages which must be used, the smallness at best of the quantities dealt with, and the essentially negative nature of the problem. Four different methods of capacitance determination were used, but no indications of any capacitance increase were found. This warrants the conclusion that the increase, if there is any due to the corona envelope, is very small. There seems, therefore, to be as yet no definite proof that corona does cause an actual change in the capacitance of a transmission line.

SUMMARY

1. The energy loss and distortion characteristics of corona can be closely approximated on an artificial line by simulating the cyclic change in line leakance peculiar to corona. This corona leakage can be lumped similarly to the resistance, capacitance, and inductance of the line.

2. Corona may cause a distortion of voltage to neutral even when there is a complete circuit for the third-harmonic currents provided by a grounded neutral.

3. The harmonics introduced by corona will not cause unusual resonance effects or extra-potential rises in the case of an unloaded line.

4. The results indicate that voltage distribution for usual corona conditions can be calculated within engineering accuracy by the methods at present in use. For this, the corona loss can be represented by an equivalent ohmic leakance.

5. Qualitative results were obtained which support the general belief that corona, in forming only at high voltages, can be effective in suppressing high-voltage disturbances.

6. The "extra-capacity effect" accompanying corona is largely a matter of definition. The presence of an envelope of ionized air about the conductors is not an essential to its occurrence. It is probable that at least the greater part of the capacitance change is apparent only, resulting from the method by which the capacitance is calculated, and from the increased line admittance to charging currents of harmonic frequencies.

In conclusion, the author wishes to thank Doctor V. Bush for suggesting and supervising this investigation, and also Messrs. M. T. Dow and R. Henriksen for their assistance in the experimental work.

Three-Phase, 60,000-Kv-a. Turbo Alternators for Gennevilliers

BY E. ROTH[1]

Associate, A. I. E. E.

THE Société Alsacienne de Constructions Mécaniques at Belfort (France), installed for the Société l'Union d'Electricité, in the Gennevilliers Generating Station near Paris, three 45,000-kv-a. sets in 1922 and another in 1924. The alternators of these sets were, at the time, the largest four-pole machines ever built, but they are now exceeded in power by the two new 60,000-kv-a. units, of 65,000-kv-a. overload capacity, that the Société Alsacienne is building for the Gennevilliers Generating Station. Like the 45,000-kv-a. generators, these new units are designed for delivering three-phase current at 6000 volts, 50 cycles, and run at 1500 rev. per min. direct-connected to 50,000-kw. steam turbines (Fig. 3).

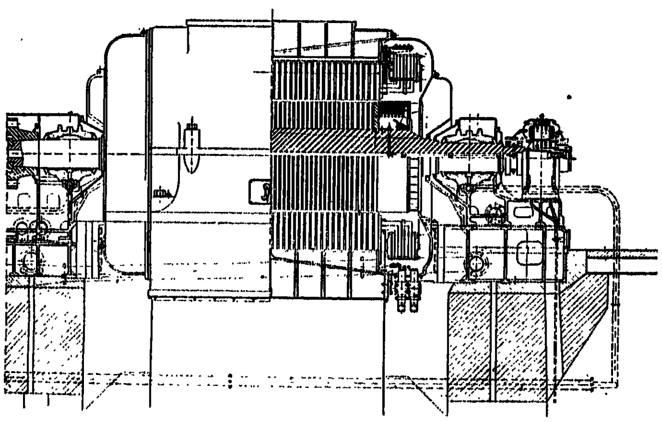

FIG. 1—LONGITUDINAL PART-SECTIONAL ELEVATION OF 60,000-KV-A. ALTERNATOR

The makers have sought to obtain the greatest strength, electrical and mechanical, in the construction of these machines, ensuring complete reliability of operation, and three years' service with the 45,000-kv-a. alternators has shown that this purpose has been fully attained. These machines have been running without accident, and tests have proved that they can even yield 55,000-kv-a. without difficulty. Indeed there have been cases where it was necessary to run them at this overload at very low power factors. In view of these good results, it is easy to understand that relatively small modifications had to be made in the design of the 45,000-kv-a. alternators to provide the 60,000-kv-a. units. It has even been possible to make their stators and rotors interchangeable.

The detailed description of the 45,000-kv-a. alternators which the author has published elsewhere[2] can thus apply to the 60,000-kv-a. units, and it seems unnecessary to repeat it here. It will be sufficient to point out, shortly, the modifications that the first alternators have undergone. However, it has occurred

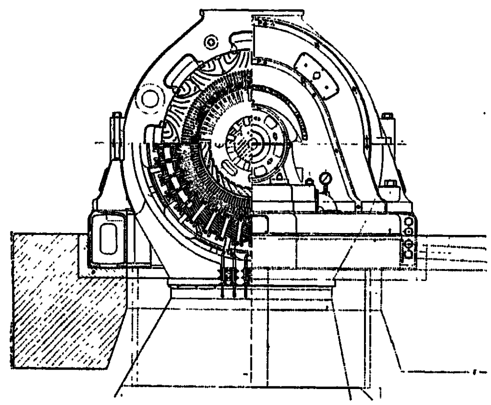

FIG. 2—TRANSVERSE PART-SECTIONAL ELEVATION

to the author that it would be interesting to reproduce in this paper, as an example of European practise, some of the photographs which have been reproduced in the

papers to which reference has been made. These photographs show assembled views of the machines (Figs. 1 to 5) as well as detailed views of the stator (Figs. 6 and 7) and the rotor (Figs. 8 and 9) in the various stages of construction. But it is desired especially to call attention to some of the unusual features of these machines which may interest the American engineer, and to point out the methods and results of tests carried out on these machines.

Comparison between the Dimensions of 60,000-Kv-a. and 45,000-Kv-a. Alternators

Some of the numerous heat tests made on the 45,000-kv-a. alternators are given later in this paper. At the

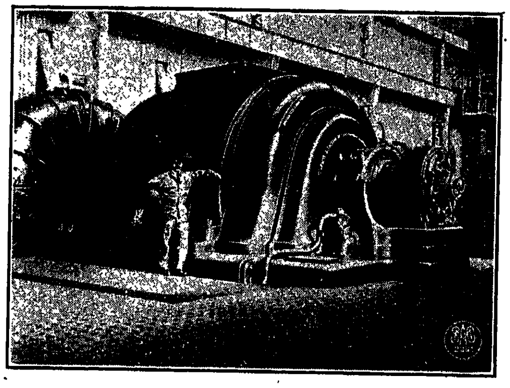

Fig. 4—View of 60,000-Kv-a. Alternator

50,200-kv-a. load (Test No. VIII) it will be noticed that the temperature rise of the copper, measured by thermocouples placed on the bare copper, inside the wrappings, was but 37.5 deg. cent., while the temperature rise of the rotor copper at the same load, as

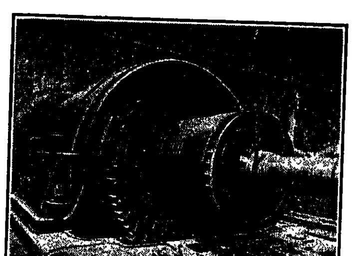

Fig. 5—Alternator in Course of Erection (Showing Details of Stator Winding and Construction of Rotor)

measured by the increase of its resistance, was only 67 deg. cent. although the power-factor was but 0.65. These small values of temperature rise, due to an excellent system of ventilation, have, as already stated, permitted the new machines to be given the same geometrical dimensions as the old, which have a total length of active iron of 278 cm. (Fig. 1).

The stator winding of the 45,000-kv-a. alternators was full pitch, while that of the 60,000-kv-a. units (Fig. 5) is a fractional pitch winding. The small increase of flux made it necessary to slightly increase the section of the rotor disks by reducing the air ducts. The resistance of the latter to the passage of the air has thus been somewhat augmented; this, however, is negligible, owing to the total section of the air ducts being very large.

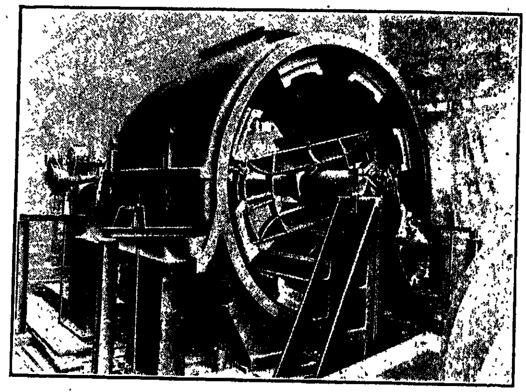

Fig. 6—Boring of Stator

For providing stability, the air-gap has been enlarged from 2.5 to 3 cm. The increase of the excitation which results therefrom is somewhat compensated for by the reduction of the armature reaction. The full-load excitation of the 60,000-kv-a. units requires 72,000 ampere-turns per pole while 65,000 ampere-turns are required in the 45,000-kv-a. units. It is obvious from the results of the test already mentioned and which corresponds to 75,000 ampere-turns, that the temperature rise of the rotor copper of the new machines will be less than 65 deg. cent. These 72,000 ampere-turns correspond to a current of 630 amperes with 19 conductors per slot or 114 turns per pole. (Fig. 9).

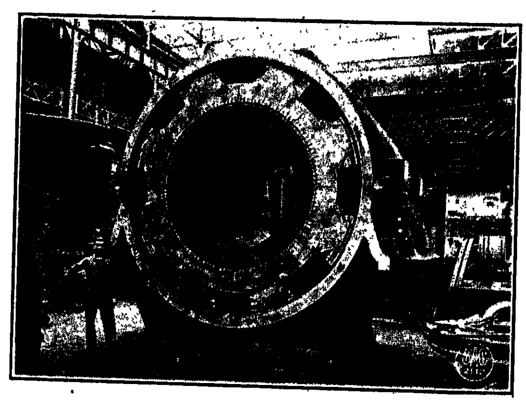

Fig. 7—Complete Stator Ready for Winding

Fig. 10 represents the stator slots of the two alternators and shows the proportions employed to provide for a very great leakage flux, constituting the most remarkable feature in these machines. Reference will be made to this feature later in the paper. The number of slots has not been altered but the section of the copper is slightly larger in the 60,000-kv-a. machines than in the 45,000 kv-a. units.

The bars in both machines are similarly constructed, and are made up of component conductors strongly insulated from each other and placed obliquely to the center line of the slot in order that they shall have identical positions with respect to the slot-field, (Fig. 11). The eddy current losses are thereby cut down to a negligible value. In fact, the examination of the reports of the heat test shows that the readings of the couples which are laid right on the copper (the first at the top of the lower coil side and the second at the top

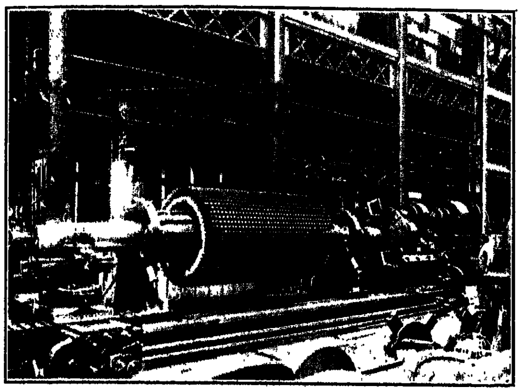

Fig. 8—Rotor on the Lathe

of the upper coil side), numbered 10 and 12 in Fig. 10, are very nearly the same. In badly designed bars, the stray losses due to eddy currents are very much greater in the upper conductor of a slot than in the lower. The fact that the temperature rise of both conductors is the same leads to the conclusion that the supplementary losses are completely eliminated.

Fig. 9—60,000-Kv-a. Rotor Being Wound

The dimensions of the air-cooler, a description of which has already appeared in the papers mentioned, have been somewhat enlarged. It will be recalled that the air describes a closed circuit. It is cooled by means of an air-cooler wherein the condensate circulates and which possesses the interesting characteristic that the amount of cooling water is maintained greater than a given minimum whatever the load may be. Thus a certain part of the water returns to the condenser immediately after leaving the air-cooler. This arrangement was made to overcome the difficulty of the losses in turbo alternators being but slightly variable with the load, whereas the amount of condensed water essentially depends thereupon; hence, there is a risk of overheating the air at light loads if the condensate alone is employed for cooling.

The total weight of the 60,000-kv-a. alternator is 162 metric tons (356,400 lbs.), without bearings and base-plate. The stator alone weighs 104 tons; the rotor, with the exciter, 50 tons; and the end-shields, 8 tons. It may be interesting to compare these weights with

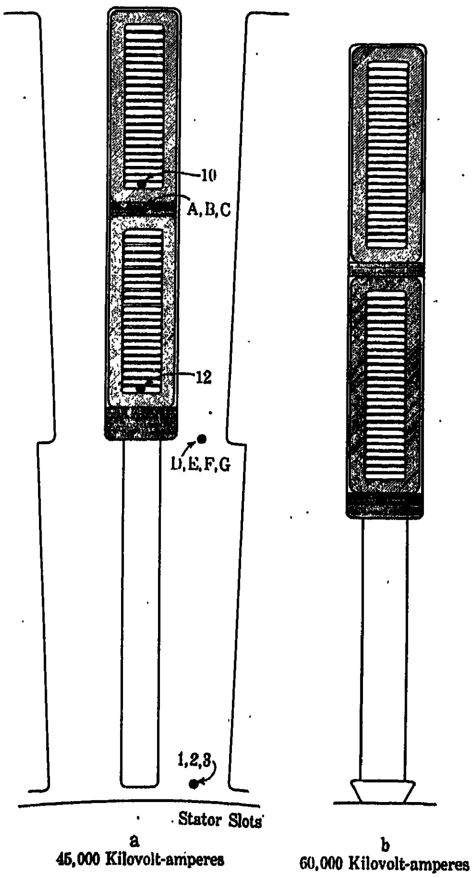

Fig. 10—Showing Arrangement of Thermocouples

those stated by Messrs. Foster, Freiburghouse, and Savage in their paper on *"Large Steam Turbine Generators,"* Journal of the A. I. E. E., October 1924, page 923. For a 62,500-kv-a., 1200-rev. per min., 60-cycle turboalternator, these authors give the following weights: stator, 93 tons without bearings and base-plate; rotor, 93 tons; end shields, 11 tons;—giving a total weight of 197 tons. The differences in weight are easily explained by the fact that the Société Alsacienne's alternator is a four-pole machine while the alternator described by those authors is a six-pole machine.

Consideration of the Advantage of Employing Leakage Slots

The leakage slots (Fig. 10) are the most interesting feature in these machines. They serve a double purpose since they first artificially increase the leakage for the stator, thus reducing the instantaneous short circuit current to a very low value, and then serve

advantageously as a channel for the cooling air. These two functions of the leakage slots will be examined in detail and it will be seen that the latter is by no means the least important.

The design of these machines has been largely influenced by the condition that, without the use of reactance coils, the instantaneous value of the symmetrical short-circuit current should not exceed four to five times that of the normal currents. The actual values are 4.17 for the 45,000-kv-a. alternator and 3.7 for the 60,000-kv-a. units. To obtain these exceptionally low values, special arrangements had to be employed.

It is a well-known fact that the instantaneous short-circuit current in turbo alternators is almost solely limited by the stator leakage, for, not only is the rotor

FIG. 11

leakage very small, but its effect is still further reduced by the presence of dampers. Therefore, neglecting the rotor leakage, the above mentioned values of the instantaneous short-circuit current in the 45,000-kv-a. and 60,000-kv-a. alternators correspond to respective inductive drops equal to 24 per cent and 27 per cent of the normal pressure with the normal current. But it is not recommended to obtain these high inductive drops by the usual means consisting of designing an alternator with a high armature reaction, because, as will be seen later on, serious disadvantages could result in the course of operation. But let us first examine the conditions which must be fulfilled in the dimensioning of the leakage slots and their advantages to the alternator itself.

The height of these slots may occasion surprise, since the same inductive drop could, in fact, be obtained by means of much smaller slots. Thus the supplementary leakage obtained by the leakage slots is the same in *a* and *b* of Fig. 12. But it should be borne in mind that on a short-circuit the normal path offered to the flux is checked and that the major part of the flux is obliged to seek its way across the slots. It is necessary, therefore, that the depth of the leakage slots be sufficient to avoid saturation of this path, since the magnetomotive force, and thus the short-circuit current which produces it, would be increased due to saturation.

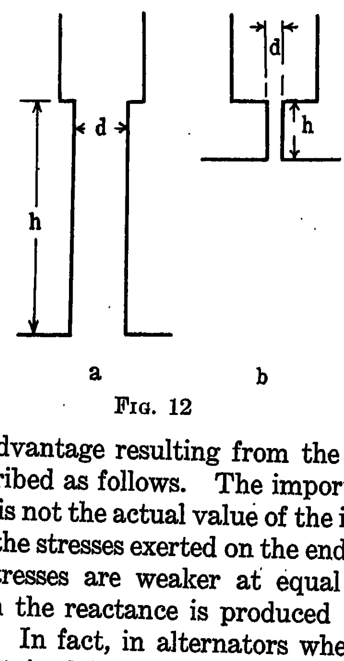
The following table shows how the inductive voltage drops caused by stator leakage are distributed in both machines; these figures are stated in per cent of the normal voltage for the normal current.

	45,000-kv-a. Alternator	60,000-kv-a. Alternator
Normal slots	2.8 per cent	4.1 per cent
End connections	9.5 per cent	12.0 per cent
Zig-zag leakage	1.5 per cent	1.9 per cent
Leakage slots	10.2 per cent	9.0 per cent
Total:	24.0 per cent	27.0 per cent

Therefore, on a sudden short-circuit, the flux which passes across the leakage slots in the 45,000-kv-a. alternator is $\frac{10.2}{24}$ or 42.5 per cent, and, depending on the instant of the short-circuit, even twice this value, or 85 per cent of the normal flux. In the 60,000-kv-a. alternator, the corresponding values are $\frac{9}{27}$ or 33 per cent and can reach twice this value, or 66 per cent of the normal flux.

Owing to these values being smaller in the 60,000-kv-a. machines, it has been possible to reduce the height of the leakage slots (Fig. 10) and thus increase the height of the core back of the slots with the same magnetic density in the core of both alternators, notwithstanding the greater total flux in the 60,000-kv-a. design.

Advantages of the Leakage Slots with Regard to the Alternator. It may be contended that these high teeth cause an increase of the losses in the teeth, but this possibility is easily compensated for by very slightly increasing the weight of the copper. And here the first advantage of these slots appears, in that they permit a greater weight of copper to be placed on the stator than that corresponding to the diameter of the bore. This greatly facilitates the construction of very powerful alternators.



a b

FIG. 12

Another advantage resulting from the leakage slots may be described as follows. The important point on short-circuit is not the actual value of the instantaneous current, but the stresses exerted on the end connections. But these stresses are weaker at equal short-circuit current when the reactance is produced by increased slot leakage. In fact, in alternators where the stator leakage is obtained by a high armature reaction, the major part of the leakage is due to the end-connections. It is consequently necessary that on short-circuit these should withstand the dynamical stress due to a flux nearly equal to the normal flux, or, depending on the instant of short-circuit, to even twice this flux. Now in the case of the 45,000-kv-a. alternator, the flux that, on short-circuit, is interlinked with the end-connections is but $\frac{9.5}{24}$ or about 40 per cent, and in the worst

conditions 80 per cent of the normal flux. In the case of the 60,000-kv-a. units, this value becomes $\frac{12}{27}$ or 44.5 per cent, and a maximum of 89 per cent. Furthermore, in machines with high armature reaction, the weight of copper to be placed in the end-connections is much greater than in a machine with a small armature reaction, and consequently, the involutes are longer and more difficult to secure and higher stress must be withstood by a part less capable of withstanding it.

We have already stated that the leakage slots perform an important function in the ventilation of these machines; reference to this will be made later.

Advantages of the Leakage Slots with Regard to the Operation. Having pointed out the advantages of the leakage slots with reference to the alternator itself, we will now examine the advantages they present with regard to operation.

One important condition with which the alternators have to comply relates to *stability of operation,* which requires a high pull-out torque; the alternator should not tend to hunt or run out of step under an accidental overload. The condition of stability is generally complied with when the machine operates on a system having a certain inductive reactance, but it is more difficult to satisfy when it may be called upon to supply a system with a capacitive load or even when the power factor is not much different from unity. Now, when the limiting instantaneous short-circuit current imposed is low, the required stability may be attained with an alternator having a high armature reaction, or, in other words, owing to stability refinements it may become impossible to design the alternator for the short-circuit current imposed. In this case, compliance with the conditions of stability leads to the design of an alternator with a rather high flux, and to the artificial increase of the leakage by means of special slots so as to obtain the proper value of the instantaneous short-circuit current.

But a small armature reaction is also necessary when it is desired to avoid *self-excitation.* This question is of sufficient importance to be dealt with in the special section following. We shall see that in this further particular, the leakage slots are extremely useful.

THE AUTO-EXCITATION OF TURBO ALTERNATORS

It is known that in certain conditions an alternator, when switched on to a capacity, may be self-exciting; that is, it may proceed to function as a generator, its magnetizing current being supplied by the capacity. This phenomenon has been described many times[3], especially by American engineers. These studies show that an alternator will be less self-exciting the larger the air-gap and the smaller the armature reaction.

Synchronous Self-excitation of Alternator with Salient Poles. Messrs. Blondel[4] and Bethenod[5] have shown that an alternator, when connected to a capacity, may be self-exciting under certain conditions if the reluctance of the path offered to the flux of direct reaction is different from that offered to the flux of transversal reaction. The current produced is at a frequency synchronous with the pulsation. We call this phenomenon "synchronous self-excitation." This difference between the reluctances of the paths of the two fluxes of reaction always exists in salient-pole alternators, but it is not so marked, being sometimes absent altogether, in turbo alternators. The synchronous self-excitation cannot therefore generally take place in these machines, and is even absolutely impossible when the rotor teeth are uniformly distributed over the periphery of the rotor.

Asynchronous Self-Excitation of Turbo Alternators. In this case, however, another kind of self-excitation may take place, but it is necessary that the rotor be provided with dampers or the rotor winding be a closed circuit. The frequency of the current produced by the machine is no longer synchronous with the pulsation when the field does not revolve synchronously with the rotor, and obtains a certain slip with regard to it. This phenomenon which we have called "asynchronous self-excitation" has been studied by Mr. Bethenod[6], who pointed out the danger it would present to turbo alternators.

The conditions of self-excitation, whether synchronous or asynchronous, are the same; the main cause is the residual magnetism. The self-excitation may in general be explained as follows:

5. loc. cit.

6. T. Bethenod. Auto-amorcage des machines, à rotors cylindriques associées à des condensateurs. Revue générale de l'Electricité, 8 September 1923, Vol. XIV, p. 307.

When starting an alternator connected across a condenser, the residual magnetism induces in the alternator a very small electromotive force. This, owing to the presence of the condenser, produces a current leading by $\frac{\pi}{2}$ which adds its magnetizing action to that of the residual magnetism. However, this effect can start the auto-excitation only at the speed by which the capacitive reactance of the condenser is slightly higher than the inductive reactance of the alternator. In fact, from this time on, the current in quadrature with the electromotive force is sufficient to magnetize the machine. As the pressure builds up, the current does likewise, one boosting the other, the phenomenon being limited only by the saturation of the alternator.

But any condenser has losses, however small they may be. Losses are also developed in the iron and copper of the alternator due to the passage of current, and these losses can be even higher than the normal losses. As the corresponding active power can be derived only from the motor driving the alternator, an electromagnetic torque has to be developed between the stator and the rotor.

The existence of this torque is rendered possible in two ways,—in the salient-pole alternators, by the dissymmetry of the magnetic circuit in which case the self-excitation is synchronous, and in the turbo alternators, by the presence of a damping circuit or the closed field circuit. In the latter case, the self-excitation is asynchronous; in fact, an active component of the current in the stator requires the presence of a corresponding component in the rotor winding for the production of which an electromotive force is required, and in order that it may be induced, it is necessary that the speed of the rotor be different from that of the revolving field, the rotor leading with regard to the field by the speed of the slip. Therefore the conditions of the existence of this component of the current in the rotor are the same as the conditions of existence of the current in the induced winding of an asynchronous generator.

The condenser is practically represented by the line which has but a small resistance. The value of the slip is then very small so that the frequency of the alternator running under the conditions of asynchronous self-excitation is not, at the normal speed, much different from the normal frequency; hence it ensues that the conditions of asynchronous self-excitation and of synchronous self-excitation are the same. The alternator is self-exciting when the capacitive reactance of the line is slightly superior to the inductive reactance of the alternator, the limiting case being where the characteristic of the line coincides with the straight part of the no-load characteristics of the alternator.

Formula Useful in Ascertaining the Conditions of Self-excitation. The conditions of self-excitation just stated can be expressed in a very simple form. An examination of the no-load and short-circuit characteristics of an alternator determines whether self-excitation will take place in the case of a line of, say, L km. length.

Study of a certain number of high-voltage, three-phase lines indicated that their capacitive reactances did not vary much from one line to another and that the value per phase (whatever the pressure), is, for 50-cycle lines, about 0.385×10^6 ohms per km. It is therefore approximately correct to multiply the value of the line pressure U, per phase, by the reciprocal of this capacitive reactance and by the length, L, in km., to obtain the charging current of the line, or:

$$\frac{10^{-6}}{0.385\sqrt{3}} \times L \times U = 1.5 \times L \times U \times 10^{-6} \text{ amperes.}$$

Multiplying this value by the transformer ratio gives the value of the charging current in the line, corrected to the pressure U_a of the alternator. It becomes

$$I = 1.5 \times \frac{U^2}{U_a} \times L \times 10^{-6} \text{ amperes.}$$

According to what has just been stated, the self-excitation will take place when the magnetizing current supplied by the line is slightly higher than the current necessary for exciting the alternator. Therefore, by reading, on the extension of the straight part of the no-load characteristic of the alternator, the number of ampere-turns corresponding to the value U_a of the normal voltage of the alternator, and determining the armature current I_a on the short-circuit characteristic corresponding to the same number of ampere-turns, the self-excitation takes place when

$$I > I_a$$

or when

$$1.5 \frac{U^2}{U_a} \times L \times 10^{-6} > I_a \text{ amperes.}$$

Application of Formula to the 60,000-kv-a. Alternator. The full lines on Fig. 13 represent the no-load and the short-circuit characteristics of the 60,000-kv-a. alternator. It will be noticed that a current $I_a = 2400$ amperes on the short-circuit characteristic corresponds to the normal pressure of 6000 volts read on the straight part of the no-load characteristic. Assuming a three-phase line at $U = 150{,}000$ volts at 50 cycles, self-excitation will take place when the length, L, of the line is such that

$$L \times 1.5 \times \frac{150{,}000^2}{6000} \times 10^{-6} > 2400 \text{ amperes,}$$

or

$$L > 426 \text{ km.}$$

Let us now compare this alternator with another of the same kv-a. output, but without leakage slots, one which also has to comply with the condition that the instantaneous short-circuit current be 3.7 times the normal current, corresponding to 27 per cent inductive

drop due to the stator leakage. As it is constructed, the leakage slots of the alternator produce 9 per cent inductive drop. Suppressing these leakage slots will give a total drop of only

$$27 - 9 = 18 \text{ per cent.}$$

It is therefore necessary that the alternator without leakage slots be designed with a sufficiently higher number of conductors to increase the reactance from 18 to 27 per cent. As the inductive drop increases as the square of the number of conductors, the numbers of conductors on the stators of the two machines should be in the ratio,

$$\sqrt{\frac{27}{18}} = 1.225$$

The flux in the second machine is reduced in the same ratio. There being imposed the supplementary condition that the magnetic circuits of both alternators be identical and all parts be submitted to the same induction, it ensues that their lengths should be in the ratio of these fluxes. Therefore, the length of the active iron of the alternator without leakage slots becomes

$$\frac{278}{1.225} = 227 \text{ cm.}$$

The copper on the periphery of the rotor of the second machine will have the same section and will then be capable of developing a magnetomotive force corresponding to 72,000 ampere-turns. Constructing the Potier's diagram for this new alternator shows that this total number of ampere-turns can be maintained only when the armature reaction is increased by 22.5 per cent by reducing the air-gap from 3 to 1.64 cm. But it is very possible that an alternator so designed will be unstable.

The no-load and short-circuit characteristics of such an alternator are traced in dotted lines on Fig. 13. Applying the above stated rule, it will be found that the self-excitation will take place if the length, L, of the line be such that

$$1.5 \times \frac{150{,}000^2}{6000} \times L \times 10^{-6} > 1140 \text{ amperes,}$$

corresponding to a line of

$$L > 202 \text{ km.}$$

This shows that with an imposed instantaneous short-circuit current of, say, 3.7 times the normal current, the alternator with leakage slots is self-exciting when the length of the line exceeds 426 km. while the one without leakage slots is self-exciting when the length of the line is only 202 km. This important advantage is obtained by a relatively slight increase of the length of the active iron from 227 to 278 cm. Let us further add that the alternator without leakage slots becomes unstable; also that in spite of an equal short-circuit current, the end connections are stressed twice as much as those of the alternators with leakage slots, and that, finally, it becomes very difficult to place the copper on the periphery of the stator.

Ventilation of 45,000-Kv-a. and 60,000-Kv-a. Alternators

The ventilating air of the rotor follows two courses: One part enters the holes in the plates supporting the fans (Fig. 1), passes into the end-connections, and escapes by the notches cut into the end-plates of the rotor, as shown in Figs. 5, 8, and 9.

The other part enters the rotor by conduits cut into the shaft (Figs. 1 and 5), thence is distributed to the air ducts, from which it passes into the air-gap and is expelled through some of the air ducts of the stator (Fig. 7), thus contributing to the cooling of the same, and is finally discharged into the frame. Therefore, the cooling air follows a radial path passing through the rotor at a rate of from 13 to 14 cubic meters per second.

We have already pointed out the importance of the leakage slots to the ventilation of the stator, as performed in the following manner. Each fan situated at the ends of the rotor delivers from 18 to 19 cubic meters per second, draws the air into the end-shields, where it penetrates between the end-connections. These latter are particularly well cooled, because of a definite spacing maintained between the involutes, permitting the air to circulate freely around them.

From the end-shields, the air enters by channels arranged in the frame (Fig. 6) and is distributed to the stator ducts. (Fig. 1). A certain amount of this air cools the core on its way across the ducts and passes into the frame; but the major part of the air penetrates between the teeth, then circulates axially in the leakage slots and follows the reverse path in the next duct, from which it also passes into the frame.

These various paths of the air and the air guide baffles may be seen in Fig. 2. It should be understood that the baffles of one type which guide the air at the intake are situated along the entire air duct and those of another type to guide the air at the exhaust are arranged all along the next air-duct.

This system of ventilation may, in a certain manner, be compared with that described by Mr. Fechheimer in his paper[7], but two essential differences exist between the two systems. First, in that of the Société Alsacienne, the air flows axially, not in the air-gap but in the leakage slots, the air-gap being, as already stated, a collector for the air of the rotor. The leakage slots are very close to the conductors and afford a much greater surface for the transmission of heat than the air-gap. The second point which distinguishes the two systems lies in the fact that in the one described by Mr. Fechheimer the air of several air ducts is discharged by a corresponding number of other neighbour-

ing ducts, while in the system described herein, the air flowing across an air duct passes in a reverse direction in the next two. The speed of the air in the leakage slots is therefore small.

This arrangement has consequently all the advantages of the axial ventilation without the inconveniences of producing very high temperatures at the center of the machines, the cooling air being distributed uniformly along the whole length of the laminations. The heat tests are the best proof of the efficiency of this system of ventilation. One will notice the fairly uniform value of the temperature rises along the whole length of the stator read during the test No. III (Table I), where the alternator, excited at the normal voltage, was submitted to a no-load heat test.

The necessary air pressure was determined experimentally by tests carried out on the apparatus as represented in Fig. 14.

Measurement of the Temperature Rise

The heat tests to which the alternators have been subjected are also reported in Table I. One short-circuit test (No. I), one no-load test, with no-excitation, which gave the temperature rise due to the ventilating air (No. II), the test No. III already mentioned, and a number of tests at various loads and various power

†Couple art.
‡Tests Nos. VII and VIII were not carried out on the same group as Nos. I to VI.

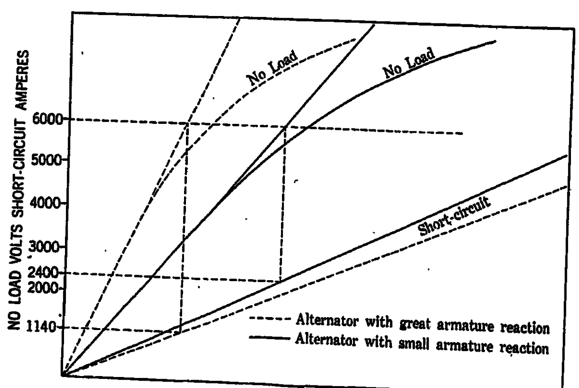

Fig. 13

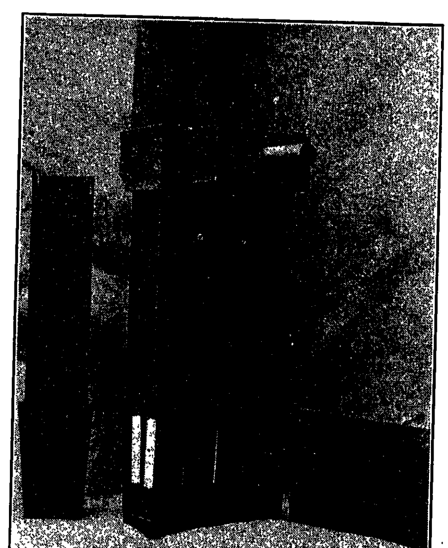

Fig. 14—Device for Measuring Pressure of Cooling Air

factors have been carried out, of which the tests No. IV to VIII have been reported.

The temperature rise of the rotor was determined by the measurement of the increase of the resistance, that of the stator by means of thermocouples. Many of these were installed throughout the stator, most of them during the construction; thus couples have been laid within the laminations in the core and in the teeth when piling up the plates. Two couples were embedded right on the copper inside the wrappings in the middle of the bars. Care was taken to connect the bars directly to neutral in order to avoid all danger during the reading.

In almost every case the couples were laid in duplicate, one serving as a spare to the other in case of breakage. The location of the couples is indicated in Figs. 10 and 15. With regard to the iron, the tables make a distinction between the couples in the core and those in the teeth, also for the measurement of the temperature of the copper by couples between the wrappings and on the bare copper.

MEASUREMENT OF THE LOSSES AND THE EFFICIENCY[8]

This article by the author contains data with regard to the efficiency of alternators at various loads. Tests have been carried out in order to measure the amount of the air by means of an anemometer and the temperature

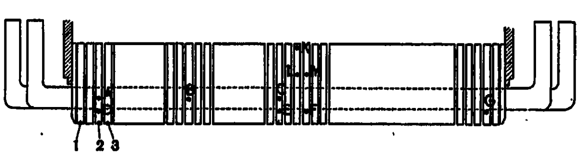

FIG. 15—ARRANGEMENT OF THERMOCOUPLES (SEE FIG. 10)

rise by means of thermo-electric couples laid at the inlet and at the exhaust of the air of the alternators. As the air circulates in a closed circuit the air chambers are not easily accessible, hence the measurement of the air speed by means of the anemometer is rather difficult. For this reason, the Société Alsacienne has elaborated the following method which has confirmed the accuracy of the first measurement. It will be an interesting matter to discuss.

Various methods have been proposed which obviate the necessity of measuring the amount of air[9]. Of these we shall mention the following: a. When it is possible to measure the losses p_0 in any running conditions (at no-load, for example), these losses are measured, as well as the temperatures t_0 at the intake and t_1 at the exhaust of the air. At the contemplated load the temperatures t_0' and t_1' of the air at the intake and the exhaust are also measured. The total losses of the machine at the considered rating will be

$$p = p_0 \frac{t_1' - t_0'}{t_1 - t_0} = p_0 \frac{\Delta t}{\Delta t_0}$$

b. It is also possible to install in the path of the air a heating resistance with which to calibrate the system. The power consumed by this resistance taking the place of the measurable losses p_0 mentioned in the first method, the total losses will be determined as indicated above.

It is obvious that these methods of measurement apply not only to the turbo alternators but also to any totally enclosed and ventilated machines. They can easily be employed on the test stands, but they often meet with certain difficulties when it is necessary, as is very often the case, to apply them to machines already erected. With particular regard to the method under the heading (b), it is easy to see that installing a heating resistance across the air channel is difficult; and it does not give the desired result because the heating is not produced at the same places as on normal running. In the method described under (a), on the contrary, the known losses, which serve for the calibration of the system, are produced within the machine, and for this reason this method should be preferred to the other one whenever applicable. However it also presents certain difficulties when it is desired to employ it for the measurement of the losses in machines already installed.

It often occurs that the no-load losses of the machine can be measured at the test stand where it is impossible to make a test under load. With these conditions, the method (a) is applicable to the machine when installed. The temperature rise corresponding to the known losses is first measured, the losses on load being deduced conversely from the temperature rise of the air. But when the machine is of such dimensions that the no-load test on the test stand is impossible, this method cannot be employed directly. This is particularly the case with the large turbo alternators. In order to measure in this case the known losses p_0 in the machine and to determine in a precise manner the temperature differences, the following method has been devised which is particularly applicable to machines the ventilation of which is performed in a closed circuit.

Calibrating the System. The known losses in an alternator may be determined by running it as a synchronous motor, but the power consumed by the latter includes not only the losses which contribute to heat the cooling air but also the friction losses in the bearings to which the losses in the driving motor (a steam turbine, for example) should be added when care has not been taken to disconnect it. However, two tests permit these constant losses to be eliminated, the alternator being run as a synchronous motor at two different voltages, the one e_2 as high and the other e_1 as low as possible. The constant temperatures being attained in each case, the temperature rises Δt_2 and Δt_1 of the air are measured, as well as the powers consumed p_2

8. E. Roth and G. Belfis. The Measurement of Losses in Totally Enclosed and Ventilated Electrical Machines, Specially the Turbo Generators. Bulletin de la Société Alsacienne de Constructions Mécaniques, No. 9, January 1915, page 20.

9. S. F. Barclay. The Determination of the Efficiency of the Turbo Alternator. The JOURNAL of the Institution of Electrical Engineers. August 1919, page 293.

and p_1. For a power $p_2 - p_1$ consumed in the machine, the temperature rise of the air would be therefore $\Delta t_2 - \Delta t_1$ and one may conclude conversely that, under the same running conditions as to rate of air flow, for which the temperature rise of the air would be Δt, the losses will be

$$p = (p_2 - p_1) \frac{\Delta t}{\Delta t_2 - \Delta t_1}$$

In order that the powers p_2 and p_1 may be accurately measured, it is advantageous to adjust the excitation to reduce to a minimum the current input.

Measuring of temperature rises. It is easy to understand that the value of the method will depend upon the

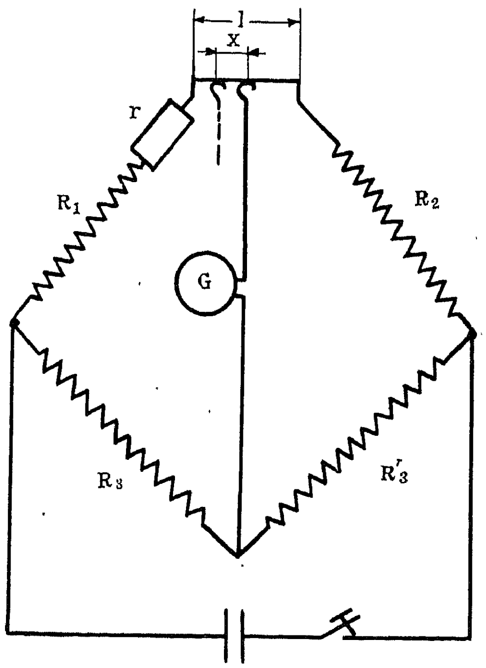

FIG. 16

accuracy with which the power and the differences of temperature, Δt, are measured. The industrial wattmeters permit of an approximation of 0.8 per cent; it will be seen later that, thanks to the test method adopted, the differences of temperature can be measured with such exactness that the accuracy of the method depends almost solely upon that of the wattmeters.

The temperatures can be measured by three different means, the thermometer, the thermoelectric couples, or the variation of the resistance of a metallic wire.

The thermometer is to be excluded from all methods of high precision; furthermore it is difficult to handle, as the apparatus for the measurement of the temperature must be installed at places highly inaccessible during the tests.

Thermocouples could be employed, but these devices also do not afford as high a precision as the method based upon the measurement of the increase of the resistance of metallic wires. It is a known fact that measurements of resistance are the most precise measurements in electrotechnics and even in physics in general. This last method has, therefore, been selected. It has the further advantage of greatly simplifying the measurements, owing to the fact that the increase of the resistance of a metallic wire in terms of the temperature

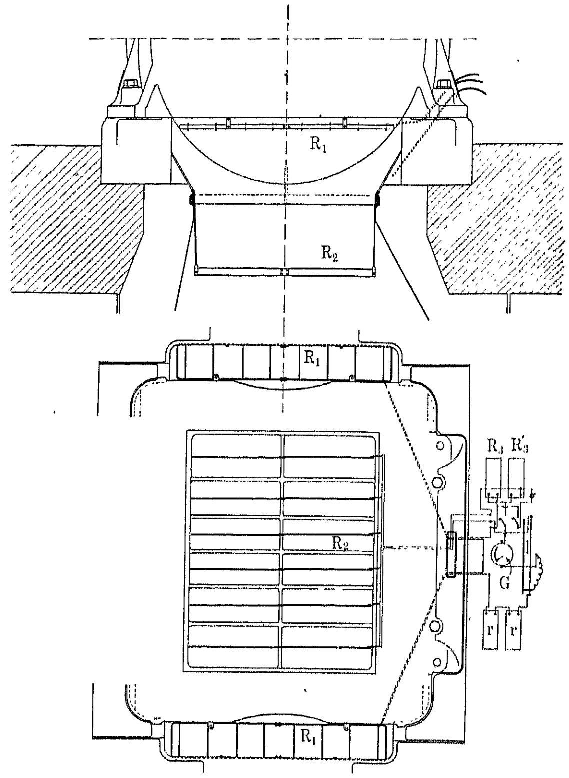

FIG. 17—ARRANGEMENT OF RESISTANCES AND APPARATUS FOR MEASURING EFFICIENCY

follows, at least in the limits that interest us, a rigorously linear law, which is not the case for the electromotive force of a thermocouple.

The variation of the resistance of a metallic wire is measured by means of a Wheatstone bridge. Direct measurements for the differences Δt between the tem-

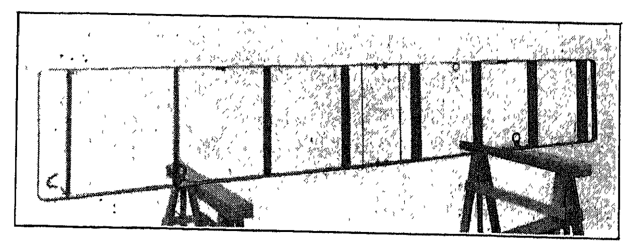

FIG. 18—ONE OF THE TWO RESISTANCES R_1 PLACED IN AIR ENTRANCE

peratures at the intake and the exhaust of the air are made, rather than measuring these temperatures separately. To this end, two resistances, R_1 and R_2, forming the two arms of a Wheatstone bridge (Fig. 16), are placed respectively at the intake, and the exhaust of the air R_1 and R_2, have equal resistances at equal temperatures.

As the temperature varies somewhat from one part of the section of the air conduit to another, the resistances R_1 and R_2 are placed so that their elements are uniformly distributed over the whole section of the conduit; the difference of the average temperature is thus directly measured (See Figs. 17 and 18).

Two other resistances, R_3 and R_4, rigorously equal, form the other two arms of the bridge. When the machine is running either as a synchronous motor or as an alternator, the values of the resistances R_1 and R_2 vary, the resistance R_2 increasing with respect to R_1. As soon as steady thermal conditions are attained the balance of the bridges is restored by means of a resistance box, r, and a wire of german silver, 1, provided with a slide which closes the circuit of the galvanometer.

The resistance, ρ, taken on the box, r, and the wire, 1, which restores the balance of the bridge, is proportional to the temperature difference desired. Designating by ρ_1 the correcting resistance for the calibrating test at the low pressure e_1, by ρ_2 that for the calibrating test at the higher pressure e_2, and by ρ the correcting resistance for the test under the considered load, there is obtained for the losses corresponding to this load:

$$p = (p_2 - p_1) \frac{\rho}{\rho_2 - \rho_1}$$

The application of this method requires, therefore, the measurement of two powers and three resistances.

Accuracy of method. It is possible to establish the values of the two resistances, R_3, and the resistance box, r, with a very high precision. The absolute values of the resistances, R_3, are of no importance. They need only be of the same order as the values of the resistances R_1 and R_2; but it is absolutely necessary that they should be rigorously equal to each other. Before being installed in the machine, the resistances, R_1 and R_2, are established with their definite connections and compared with each other. To this end, the elements being intermingled, they are placed for a sufficient length of time in closed boxes to make sure that the temperature of all elements is the same. This is ascertained by the fact that when replacing, R_1 or R_2, or conversely, the balance of the bridge is not disturbed. The accuracy of the values of the ratio

$\frac{\rho}{\rho_2 - \rho_1}$ is thus very high so that the accuracy of the method depends almost solely upon that of the wattmeters.

When making the calibration measurements it is advantageous, in order to increase the precision, to disconnect the alternator from the turbine; and this procedure should be followed every time the conditions of operation of the power plant permit it.

The possible error in the losses of one alternator, the efficiency of which is 96 per cent, or nearly so, varies from four to five per cent, with four per cent losses. The error in the efficiency therefore lies between:

$$4 \times 0.04 \text{ and } 4 \times 0.05 \text{ per cent,}$$

say, between 0.16 and 0.20 per cent.

Discussion

W. F. Dawson: The author is to be particularly congratulated on the production of a very fine machine. It has shown low heating, many novel and ingenious ideas, good mechanical engineering, and, I should say, very good efficiency. But there is one feature of the design that is quite startling to us in the United States. I know I speak for myself and for my immediate colleagues although I do not know that I speak for other manufacturers in this country.

Mr. Roth has laid particular stress on the fact that, by means of his leakage slot, he has achieved very low short-circuit current, current as a result of sudden short circuit. He has also pointed out that he has done this in preference to using very high armature reaction and a correspondingly low flux. Nevertheless, his armature reactions are proportionately higher than we would feel safe in using.

If we go back to the *Electrical Review* of London, April, 1923, we find there the saturation and impedance curves (page 646, issue of April 27th, 1923). The "saturation," 6000 volts is, expressed in field amperes, about 136 amperes. The short-circuit impedance at 4200 amperes is approximately 270 amperes. We feel that in designing alternators, particularly those to carry inductive load, the excitation required for normal ampere short-circuit impedance should not be much in excess of the excitation required at normal open-circuit voltage.

I understand that it is the practise of many European designers to allow a high short-circuit impedance, making a machine in which the full-load field excitation is three times the open-circuit excitation.

I also understand that somehow in general they are successful with it, probably because the increment of the load is small compared with the total load and perhaps, too, because of the more general use of automatic voltage regulators. I have had at least two or three glaring cases in my own practise, in which, before I realized the importance of designing for "voltage stability," the voltage would break down at or about full load. One case was in a cotton mill where one turbo alternator was carrying the entire load of the mill and, according to the calculations which I learned later how to make, the machine should have had a voltage breakdown at about 2300 kw.; it was rated at 2500 kw. I furnished a new armature which had lower armature reaction and, of course, higher flux, and the trouble disappeared.

I have had other cases into which it is not necessary to go; we have also noticed it particularly in the case of ship propulsion machines where one turbo alternator is to take care of the induction-motor load. That machine, or a group of machines, will be running along satisfactorily, but rough sea will increase the load on the motors, and the voltage falls faster than the amperes increase; hence the kv-a. is reduced and the motors break down.

I should like the author to tell whether he has had any such experience.

Philip Torchio: Mr. Roth's paper gives an excellent illustration of the progress in large turbo alternator design. Some of the special features of his machines will undoubtedly be commented upon by expert designing engineers. From an operator's standpoint, I wish to express my sincere appreciation of the remarkably low temperature rises of the copper in the stator and the rotor. The long narrow slots with an abundance of radiating area, the winding bars of the armature, with their careful assembling to eliminate eddy-current losses and a combination of axial and radial ventilation, have been used to secure results which are superior to any with which I am acquainted.

In making this statement I wish to add that I have not had the time to analyze closely how much the results are influenced by the differences in number of poles and the relative capacities of the machines compared. Mr. Roth has already mentioned how the difference in number of poles for machines of same capacities affects the total weights of such machines. Undoubtedly to some extent the number of poles imposes limitations upon the temperature rises. The employment of leakage slots may, however, be of a decided advantage in giving remarkably low temperature rises.

As to the advantage of reducing the short-circuit current, I shall be very much interested to learn of the comments of designing engineers. In our practise we have, for more than 13 years, considered it essential to the safe operation of a large system to install reactors between generators and buses so as to protect the main bus against sort-circuit failures in generator windings. In such installations, therefore, the reduction of short-circuit current on sound generators is limited by the external reactors, and designers may not find it necessary or desirable to employ leakage slots. This is a problem that should receive consideration in the discussion.

C. M. Laffoon: These generators are unique, in that certain design features are carried to rather extreme limits. The author states that the 45,000-kv-a. turbo generators, which were installed in the Gennevilliers station in 1922, were the largest four-pole turbo generators built up to that time, This statement is somewhat liable to misinterpretation because these are 50-cycle machines and the design and construction of a given size, four-pole generator, operating at 1500 rev. per min. are not so difficult as the design and construction of a four-pole, 60-cycle generator which operates at 1800 rev. per min. At the time these Gennevilliers generators were installed, they were rated at 40,000 kv-a. At the same time the Westinghouse Company was installing the first of the Hellgate generators which were rated at 43,750 kv-a., but were six-pole, 1200-rev. per min. The Westinghouse Company has since built generators of this same kv-a. rating but of four poles, 1800-rev. per min. Recent tests on these generators show that they will carry 50,000 kv-a. at 80 per cent power factor and do not exceed the standard guarantee of 60 deg. cent. temperature rise on the armature winding and 90 deg. on the field winding. The Westinghouse Company has also built 62,500-kv-a. generators for the Brooklyn Edison Company, but these were of six poles and 1200-rev. per min. At the present time a four-pole, 1800-rev. per min. 62,500-kv-a. 80 per cent power-factor turbo generator is being developed by the Westinghouse Company and 1800-rev. per. min. generators with ratings as high as 75,000 kw. and 90 per cent power factor appear feasible to build and operate.

It is to be noted that this generator is being wound for 6000 volts, which is a relatively low voltage for 60,000-kv-a. rating. In the United States the majority of central stations generate at voltages varying from 11,000 to 13,800, and with some companies there is a decided tendency to specify a final insulation test voltage of three times normal plus 1000 instead of the standard insulation test of twice normal plus 1000. However, some utility companies are considering the advisability of having generators wound for lower voltages and solidly connecting the generators to step-up transformers without any intermediate circuit breakers. In this case the final insulation test voltage would be on the order of four times normal plus 1000. On the other hand, other companies in the far west are considering 16,500-volt generators. At the present time there does not appear to be sufficient data available to determine the maximum voltage stresses due to switching, short circuits, and lightning to which the generator windings may be subjected during actual service conditions. Until these data are available, it will be difficult to determine the voltage and insulation strength which will give the greatest protection against over-voltages and still not seriously affect the cost and the reliability of operation from the standpoint of temperature.

In going over this paper the following outstanding features are of paramount importance:

1. Small physical dimensions.
2. Low short-circuit ratio, i.e., a low ratio of no-load field ampere-turns to the field ampere-turns which are required to maintain full-load sustained armature current.
3. High leakage reactance.

In comparing the physical dimensions of this 50-cycle generator with those of a four-pole, 60-cycle, 1800-rev. per. min. generator of the same kv-a. rating, it is noted that the overall length of the active iron including the ventilating ducts is considerably less than that required for the 60-cycle generator. This is partly due to the fact, as previously indicated, that, for a given rotor diameter, the design and construction of a 50-cycle generator are less difficult than they are for a 60-cycle generator of the same rating and number of poles. Since the mechanical stresses in the rotor body and retaining rings are proportional to the square of the peripheral speed, approximately 20 per cent more ampere-wires per inch of wound periphery can be obtained for a given rotor diameter for the 50-cycle generator than for the 60-cycle generator on the basis of the same number of poles. In either case, for a given short-circuit ratio, the kv-a. output is proportional to the product of the total flux, rotor ampere-turns, and rev. per min. Hence, the length of the active iron of the 50-cycle generator would be appreciably less than that of the 60-cycle generator and would be equal to that of the 60-cycle generator multiplied by the inverse ratio of the total flux in the machine. Since the iron loss varies approximately as the second power of the flux density and about as 1.2 power of the frequency, the relative total flux for the two cases will depend on the effectiveness of ventilation for each generator. An examination of the temperature data of Table I shows rather high stator-iron temperatures as compared to the temperatures on the bare copper. This indicates that the stator iron is worked at rather high magnetic induction and consequently this feature also tends toward a short machine.

From Fig. 13, the short-circuit ratio of this 60,000-kv-a. generator is approximately 0.475. This same value was obtained from the specified dimensions and design data which were given for the armature and field windings. The short-circuit ratio of a Westinghouse generator of the same rating would be on the order of 1. Similarly, the full-load field ampere-turns are approximately 3.1 times the no-load field ampere-turns, whereas, in the case of the Westinghouse generator, the ratio is about 2 to 1. This means that the armature ampere-turns are high as compared to the no-load field ampere-turns and a small change in the armature load current produces a large change in generated voltage and kw. output. Fig. 2 herewith shows the relation between armature current and voltage, armature current and kw. output, and kw. output and voltage for the 60,000-kv-a. Gennevilliers generators and for a 62,500-kv-a., 60-cycle, 1800-rev. per min. generator with the field excitation corresponding to full rated kv-a. at 80 per cent power factor. The curves for the 60,000-kv-a. Gennevilliers generators were determined from the specified design data and physical dimensions of these machines, and the no-load and short-circuit saturation curves of Fig. 1 herewith. The curves in Fig. 1. are the same as given in Fig. 7 of the paper for the 45,000-kv-a. generators but modified to suit the design constants of the 60,000 kv-a. generators. An analysis of the load curves in Fig. 2 shows the following comparison of the stability characteristics of the two generators when operating at 7 per cent power factor loads, and with a field excitation corresponding to full-load 80 per cent power factor conditions:

1. The maximum kilowatt output of the Westinghouse generator is 106 per cent, whereas that of the Gennevilliers generator is only 100.5 per cent.

2. The Westinghouse generator will deliver 100 per cent kilowatt output with an armature-current range of 100 to 138 per cent, whereas the Gennevilliers generators will deliver full kilowatt output over an armature-current range of 100 to 108 per cent only.

3. The rate of change of terminal voltage with respect to kilowatt output, at the point of 100 kw. output, is approximately five times as great for the Gennevilliers generator as for the Westinghouse generator.

This comparison shows that the Gennevilliers generators,

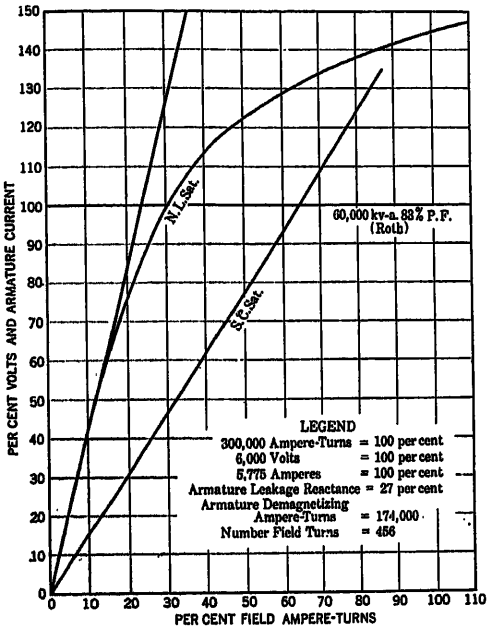

FIG. 1—NO-LOAD AND SHORT-CIRCUIT SATURATION CURVES 60,000-KV-A., 50,000-KW., 83 PER CENT POWER-FACTOR, 6000-VOLT, 50-CYCLE, 1500-REV. PER MIN., 5775-AMPERE GENNEVILLIERS GENERATORS

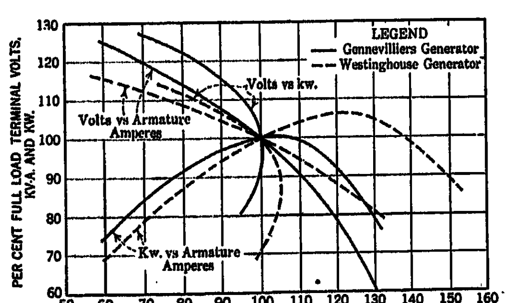

FIG. 2—LOAD CHARACTERISTICS FOR 50,000-KW. TURBO GENERATORS 80 PER CENT POWER FACTOR AND CONSTANT FIELD EXCITATION

which are designed with a low short-circuit ratio are much more sensitive to sudden changes in load than the Westinghouse generators which have a short-circuit ratio which is more than twice as large. Hence, when operating alone or in parallel with other generators which have the same characteristics, it would be necessary to provide voltage regulators in order to maintain reasonably constant voltage for rapidly changing loads on the system. The application of quick-acting voltage regulators to these machines is difficult because of the extremely wide range in field current required in going from no-load to full-load operating conditions.

If these generators were operated in parallel with other generators which have greater stability under changing load conditions, that is short-circuit ratios of one or more, it would be necessary not only to provide high-speed voltage regulators but the characteristics of the voltage regulators and of the governors on the driving turbines would have to be carefully designed to meet the particular conditions. But even then, there is always the possibility that hunting action may take place between the generators with poor and good regulating characteristics and reach such magnitudes as to cause the machines to pull out of step.

In the case of high-voltage transmission system, the design of the generators should be such that the armature ampere-turns are small as compared to the no-load field ampere-turns; that is, the short-circuit ratios should be high.

A generator designed with a low short-circuit ratio has considerably smaller dimensions than one designed for a high short-circuit ratio on account of the fact that the portion of the field ampere-turns which is used to give stability in the high short-circuit ratio machine is used to give kv-a. output in the case of the generator with the low short-circuit ratio. There is no doubt but that generators with short-circuit ratios as low as 0.475 can be operated satisfactorily with hand regulation on systems which have reasonably smooth load curves, as well as with automatic voltage regulators on systems with varying loads, provided the voltage regulators and turbine governors are designed with the necessary characteristics. However, there is no doubt that such generators require careful attention and are likely to give trouble during transient disturbances or sudden load changes. The extent to which it is desirable to reduce the short-circuit ratio, and hence increase the output for given physical dimensions depends, to a large extent, on the load characteristics of the system on which the generator is to operate, the characteristics of the generators which operate in parallel, the characteristics of the voltage regulators and turbine governors, and the amount of attention the operators give to the machine. Our own experience and observation indicate that turbo generators which have short-circuit ratios of approximate unity give satisfactory operation on the average central-station system in this country. However, this value of short-circuit ratio can and must be widely departed from in the case of generators which operate on systems or central stations in which greater or less generator stability is necessary.

The leakage reactance of the armature winding of the Gennevilliers generators is unusually high for turbo generators. A large portion of this reactance is obtained by providing leakage slots immediately above the slots for the main winding. If it is necessary to limit the initial values of short-circuit current to values comparable with those delivered by slow-speed waterwheel-type generators and the reactance must be within the generator, this is an attractive method of obtaining a high reactance. The mechanical forces on the end turns are reduced and the increase in reactance due to the air slots does not materially increase the iron loss in going from no-load to full-load conditions. However, it must be remembered that the use of these slots increases the over-all diameter of the machine, the cost, and the value of the iron losses. The increase in diameter and cost are partially offset by the fact that more room is obtained for the armature copper. An increase in diameter not only adds to the weight but also the shipping difficulties. The iron loss in the stator teeth is usually about one-half of the value of the loss in the core. The additional tooth projections increases the iron loss in the stator teeth about 60 per cent and this corresponds to an increase in the total iron loss of approximately 20 per cent. In the case of particular generator, the additional 20 per cent increase in iron loss corresponds to 0.15 to 0.20 per cent reduction in the generator efficiency.

The leakage reactance of a 60-cycle, 1800-rev. per min. West-

inghouse turbo generator of the same rating would be from 15 to 18 per cent, and the end turns of the armature winding are sufficiently well braced to withstand a three-phase short circuit at the generator terminals under no-load initial conditions and 110 per cent of normal rated voltage, as required by the 1925 A. I. E. E. Standards. So far as the initial values of the short-circuit currents are concerned, this condition corresponds very favorably with the actual conditions under full-load operation. In machines of this class the percentage of winding failures due to short circuits has been very small. In general we feel that the end turns can be sufficiently well braced to withstand short circuits that occur under usual operating conditions when the leakage reactance of the generator is 10 per cent and above. If still greater protection is desired it can be obtained by making further improvements in the bracing instead of increasing the leakage reactance by a method which involves an increase in cost and overall diameter, and a decrease in the generator efficiency of 0.15 to 0.12 per cent.

A comparison of the temperature rises obtained by detectors C, 10, and 12 show that when carrying 50,200 kv-a., the temperature rise on the bare copper at the midway axial position is only 37.5 deg. cent or 10 deg. higher than the temperature rise of detector placed between the conductor sections. Using this same temperature difference, the temperature rise of the bare copper near the ends of the machine would be 50 to 56 deg. cent. The iron temperatures vary over quite a wide range, being particularly high in the teeth at the ends of the machine and in the core at the middle of the machine. The temperature rises of the armature and field windings compare very favorably with corresponding temperatures obtained on Westinghouse generators which have a similar system of ventilation. This particular form of the multiple-path radial system of ventilation is exceptionally well worked out from the standpoint of utilizing the frame space behind the stator punchings, and gives excellent results in stator and rotor ventilation. The air requirements for the generator are approximately 105,000 cu. ft. per min. and the author states that approximately 26.5 per cent of the air passes through the rotor body. This is an unusually large percentage for the rotor and no doubt is responsible for the low temperature of the field winding.

In order to determine the losses of turbo generators when operating under normal load conditions, it is necessary to know the volume of cooling air and its temperature rise for any particular load condition. Various methods have been suggested and used for measuring the amount of air passing through the machine. When the air discharges to the atmosphere the air volume can be determined with a good degree of accuracy by measuring the velocity head at the discharge from a specially designed stack or nozzle. The discharge velocity can be made practically uniform over the entire discharge section by properly designing the stack and passing the air through fine-mesh screens as it leaves the generator. However, the most promising method is the one suggested by the author, in which the generator is operated as a synchronous motor under no-load conditions and the electrical input and final temperature rise of the cooling air are measured for two widely different values of voltage. If temperature detectors of the thermocouple or resistance type are properly placed in the inlet and outlet air ducts and due care exercised in making the measurements, the air volume can be determinded with a satisfactory degree of accuracy. Since most large turbo generators cannot be tested at the manufacture works under normal load conditions, it seems very essential that all such generator units should be so arranged that the steam end can be disconnected and the generator operated as a synchronous motor. The operating companies should have sufficient interest in the performance of the machines to be willing to cooperate with the manufacturers in making the tests.

Briefly summarizing, the 60,000-kv-a. turbo generators as described by Mr. Roth are exceedingly interesting on account of:

(1) The small physical dimensions which result from the following:

a. The generators are designed for 50 cycles at 1500 rev. per min., and consequently the stator iron can be worked at a higher magnetic induction than in a 60-cycle generator;

b. The short-circuit ratio is unusually low; that is, the portion of the field ampere-turns which is used to give stability in the case of a Westinghouse generator is used to give kv-a. output in the Gennevilliers generators; and

c. The ventilating system provides excellent cooling for both stator and rotor.

(2) Low short-circuit ratio, which results in a machine that is sensitive to load changes and is likely to be very unstable when operated on a system with rapidly changing load. The application of voltage regulators is more difficult on account of the wide range of exciting current which is required for a given load change.

(3) The high armature leakage reactance, which is obtained from the additional slots, provides short-circuit protection and the additional reactance which is secured does not materially increase the core loss under stable load conditions. However, this method of obtaining high reactance involves an increase in cost and overall diameter, and 0.15 to 0.20 per cent reduction in generator efficiency.

C. J. Fechheimer: A few points of interest in this paper will be pointed out in this discussion.

1. The scheme of stator ventilation is unique, as the circumferential system is combined with the axial system. The air which flows circumferentially does not pass through the stator teeth and into the air gap, but the air that flows axially first flows radially inward and then axially through the leakage slots.

Referring to Fig. 2, you will notice that at the back of the core through which the air passes first axially to get into the radial slots, there are eight openings distributed about. The air passes down, radially, in the vent ducts and then, in the same vent ducts, some passes around circumferentially and goes out. Some of the air goes farther radially between the coils and gets into the leakage slots and then moves axially. You see that on one side are shown one kind of guide for the air, and on the other side of the line the guides are arranged differently. Now on the right side of the line, the guides are for the air coming in, and to the left they are for the air going out; that is, the air moves axially and then out, radially, in the next vent duct, and that is the one at 45 deg. to the left of the division line. It moves axially through the leakage slot.

It would seem that the objections which were raised to the circumferential system of ventilation are believed not to apply to Mr. Roth's machine.[1] In the tests on the model for circumferential flow described in my A. I. E. E. paper in 1924, the air flowed radially through the vents and then circumferentially through the air gap. Although an analytical study of Mr. Roth's system of ventilation has not been made, the low temperatures obtained and the comparatively small dimensions indicate that the system is excellent. It would seem that the supply of air to the leakage slots is sufficient to maintain comparatively low temperatures in the tooth belt where the material is worked the hardest.

2. The method which Mr. Roth uses for measuring the losses and air volumes at full load is novel. Mr. Roth assures us that he can obtain accuracy by calibrating the system, operating idle as a synchronous motor with known total losses at two different voltages. In the equation on page 10, what is the

1. *An Experimental Study of Ventilation of Turbo Alternators.* TRANS. A. I. E. E., 1924, pp. 486-488.

order of magnitude of $\Delta t_2 - \Delta t^1$? I presume it is about 10 deg. cent., and to obtain accuracy these temperature rises must be measured with extreme care.

The measurement of the temperature rises of the air by means of resistance coils connected in a Wheatstone-bridge network is one that is frequently used, and if proper precautions are taken, it should lead to accurate measurements. With small temperature rises, it is necessary to measure resistances with extreme accuracy, as a one-degree change in temperature corresponds approximately to only 0.4 per cent change in resistance; or, if the temperature rise is 10 deg., it is necessary to read to 0.04 per cent if the error is to be not over 1 per cent. In some of our work, temperature rises of the order of only two degree are obtained, and then it is necessary to read to 0.008 per cent. While, with extreme care, such measurements of resistance can be made, there are possible sources of error, such as those due to contact resistance or those which might arise from the stretching of some of the wires, and this introduction of considerable errors.

In the early work on air-volume measurements by the thermal method at the Westinghouse Company, resistance measurements were made, but they were abandoned partly because of the necessity for great precision in measurement and partly because a few of the wires stretched and the resistance was consequently changed. We have since been using large numbers of thermocouples connected in series, and, for the most part, have been able to secure very reliable results. We can read our volumes within about 1 per cent. Of course, if only a few thermocouples are used, this method is not recommended, as a reliable average is not then obtainable.

3. The volume of air through the rotor seems to be very high. In conversation Mr. Roth explained to me the method which he used for measuring it. I think that the method is of sufficient interest to warrant his telling the members of the Institute what it is.

4. The device shown in Fig. 14, for measuring the pressure of the cooling air, is a model of part of the machine in which the flows are imitated as accurately as possible. I should inquire of Mr. Roth how close the agreement was between the pressure measured in the model and the pressure measured in the machine. I am a great believer in imitating in a model, conditions in the actual structure, but in this, care must be exercised, as sometimes the conditions are extremely difficult to imitate with sufficient accuracy.

5. Mr. Roth states that with a salient-pole alternator, the self-excitation is synchronous. It may be of interest to those who have not noted it before that it is possible to increase the load on a salient-pole alternator gradually when it is being excited by condensive reactance until, at a certain load, the alternator pulls out of step and runs at a speed slightly above the frequency of the line. In other words, in a salient-pole machine just as in a turbo alternator it is possible to have self-excitation and operate as an asynchronous generator. One of the oscillograms in the discussion referred to by Mr. Roth shows this very clearly.[2]

E. H. Freiburghouse: I agree in general with what Mr. Laffoon has said as to the principles governing the limit of electrical stability of alternators, and I, too, question whether these generators which have been described by Mr. Roth possess the necessary margin of stability.

Nevertheless, Mr. Roth has informed me that generators having these characteristics do operate successfully and that the power-station people do not find it necessary to employ voltage regulators. He states that voltage regulators have been installed but their use has not been found necessary.

Some years ago, the General Electric Company rebuilt a large foreign-made, turbine-alternator in which they even increased the originally high synchronous impedance. There have always been doubts about the stability of that generator; however, it has now been operating satisfactorily for seven years, although the excitation for synchronous impedance is 2.04 times that for normal voltage at no load. The above is an abnormal ratio which we do not advocate. Instead, we usually make the ratio less than unity.

The deep, partially closed leakage slots which Mr. Roth has employed to increase the reactance also inherently make it necessary to assemble the stator bars axially from the end of the core. Obviously, the fit of the coil cannot be so close in the slot as it would be if it were inserted radially under pressure from the air gap or open end of a slot. However, his machine is much shorter than we are building for that output.

We do not believe that 27 per cent reactance is necessary to insure the safety of the turbine-type alternator which has its stator winding laced at the ends to supporting rings. This machine as built in America is apparently flexible and strong enough to withstand many thousand dead short circuits without permanent distortion of the end structure. I recently witnessed a number of dead short circuits upon generators rated 35,300 kv-a. upon which there was no permanent distortion whatsoever.

Referring to the heating of these generators as given by Mr. Roth in Table I, we find that the temperatures obtained during the open-circuit run No. III were fairly uniform throughout the core; however, this was not the case during the short circuit test No. I. On tooth G, Fig. 15, the rise was 70 deg. cent.; on tooth F, 27 deg.; and on tooth E, 26 deg. G was in the second package of iron from the end of the core whereas the others were in the middle of the core. I venture to say that the extra heating of tooth G was caused by flux from the magnetomotive-forces of the stator winding outside of the core. We are interested to know what temperatures were obtained at the other end of the core by couples 1, 2, and 3.

W. B. Kirke: This paper brings out new methods of incorporating characteristics of high reactance without obtaining excessive armature reaction. At the same time the use of leakage slots provides an effective method to keep the temperature rise within low limits.

The first characteristic of high reactance is provided for in a great many systems in this country by the use of external reactors in the circuit connecting the generator to the bus. Such reactors not only aid in keeping the voltage near normal with a generator short circuit but they also reduce the interrupting duty on the generator circuit breakers. On the other hand, if the reactance is built into the machine by the use of leakage slots or other means, a generator short circuit means dropping the voltage of the bus section fed by that unit.

Increasing the stability of the machine is a very desirable feature. As systems are more extended and more power plants interconnected, one wonders if ever a condition will exist when the extreme ends of an interconnected system will start rocking, due to lack of stability of the interconnected system. Any measure tending to increase the stability of a single unit will aid in stabilizing a large system consisting of many such units.

The use of leakage slots would seem to indicate a considerable advantage in ventilating the unit. With the maximum size of turbo generators steadily increasing as the size of systems and interconnection facilities develop, capacities of 100,000 kv-a. will soon be required. Any method which indicates an improved means of ventilation should be given thorough analysis by designing engineers.

Robert Pohl: "The most interesting part of Mr. Roth's paper is his advocacy of leakage slots below the main stator slots. This design is for obvious reasons superior to the deep slot bridges advocated by Miles Walker many years ago, but somewhat similar in principle to the practise of some makers to use much deeper open slots than necessary for the winding. The author has convincingly demonstrated the advantages of

2. TRANS. A. I. E. E., 1920, Vol. XXXIX, p. 1637.

his design. I should like to say, however, that the properties of such leakage slots do not appear to me generally advantageous but only in special cases. In the first place, why employ so high a reactance as 27 per cent? If Mr. Roth's 60,000-kv-a. alternator had been made without leakage slots, its reactance of 18 per cent would have been fully high enough for all ordinary requirements and perhaps already too high for stations with feeder reactances and a poor power factor. In Europe we have often to deal with station power factors much below 0.8 down to 0.6. In such cases the increase of reactance makes itself seriously felt in the size and to some extent in the efficiency of the alternator.

As to the author's comparison of the two methods of obtaining high reactance, leakage slots or increased electric loading, one misses the third alternative, i.e., a separate reactor. It is obvious that an alternator with separate reactor will, as regards stability, auto-excitation, and stresses on end connections, behave exactly as a corresponding alternator with leakage slots and equal total reactance. A short circuit on the alternator terminals need hardly be feared. It seems to me that the leakage-slot design with its appreciable increase in the stator dimensions is the more expensive way of creating the desired additional reactance. If so, it can only be justified by the remaining advantage, i.e., the improvement in ventilation. This seems to me the decisive point. Here one has to distinguish between bipolar and multipolar designs. In bipolar turbo alternators the output is mostly limited by the temperature rise of the rotor. The stator winding is generally cool enough when placed in the ordinary way in close proximity to the rotor. Hence there appears to be no cause for changing this practise. The same applies to smaller four-pole machines with solid rotors. In the larger four-pole and even more so in the six-pole designs with built-up rotors the ventilation of the latter is more effective and the limiting temperature may be found in the stator winding. Here it may well be advantageous to employ an otherwise unnecessary depth of slot or leakage slots after Mr. Roth's proposal if there is no other way of improving the ventilation.

Another way of improving the cooling of altenators is the use of hydrogen or other gases superior to air as cooling media.

Franklin Punga: I congratulate Mr. Roth on his contributions to developments in the design and construction of large turbo generators, and in particular on the means by which he was able to increase to 60,000 kv-a. the rating of the 45,000-kv-a. generator without altering the external dimensions.

Regarding certain features I should like to make the following observations:

I thoroughly endorse the employment of a stator slot provided with a large open portion at the end opposite the air gap. This is very useful for ventilation purposes. In the design which I some time ago proposed to the Thyssen firm, and contrary to the design of Mr. Roth, the lower third of the slot was widened as shown in the accompanying illustration of the slot, Fig 3. The principal reason for this relates to winding construction technicalities. In the normal partly or entirely closed slot, the conductor has to be inserted axially. This makes it necessary to make a relatively great allowance for clearance between the side of the slot and the insulated conductor; otherwise the insulation on the conductor is liable to be harmed in the process of being inserted into place in the slot. Should any repair of the winding ever be necessary it is exceedingly difficult to remove such a conductor from the slot. In designs in which the conductor is inserted radially into an open slot, it is practicable to allow less clearance between the insulated conductor and the sides of the slot. This is desirable for several reasons, such as (1) obtaining a better space factor, and (2) decreasing the liability to corona phenomena. When employing my design of slot the insulated conductor is first introduced axially into the space in the lower third and is then pressed radially upward into place, the space available in the ventilating ducts being convenient for the application of the necessary radial pressure.

But this design of slot fulfils a second important purpose. It is well known that if the tooth saturation is too great, the flux passing parallel to the sides of the slot occasions a considerable copper loss. For this reason it is customary to employ a relatively low no-load tooth saturation (some 16,000 lines per sq. cm.), so that at full load the value of 20,000 lines per sq. cm. shall not be exceeded. Now the difference between the tooth saturation at full load and that at no load is chiefly dependent upon the distorting ampere-turns. The decreased tooth section in the lower third of the slot consequently serves as insurance against too great saturation in the portions where the copper is located and will be found especially valuable in turbo generators with a cos near ϕ unity.

Furthermore, the slot leakage is of course also decidedly increased, although not so much as in the case of the turbo generator designed by Mr. Roth. The advantages which Mr. Roth mentions, relating to relatively great slot leakage, are all of them correct, but a disadvantage of the great slot leakage ought not to be overlooked, namely, the radial saturation of teeth at particular parts of the circumference on the occurrence of sudden short circuits. For instance if we represent

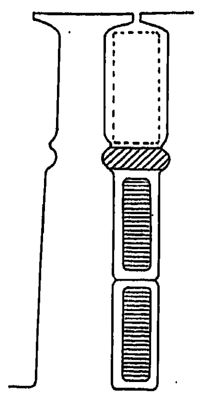

FIG. 3

the leakage of one slot by a vector, this will be of uniform magnitude and direction until we come to a place on the circumference where one phase winding is completed and the next phase winding begins. In a four-pole machine with two conductors per slot, and 100 per cent winding pitch, there are on the circumference twelve such places. The slot leakage vector moves through 60 electrical degrees and the consequence is that at these points a flux represented by a vector of equal magnitude passes through the tooth and into the laminations behind the slots. Consequently in such a machine at short circuit there would be complete saturation of twelve teeth equally distributed around the circumference. This would decrease the effectiveness of the great slot leakage. In this respect the use of fractional-pitch windings is of advantage since the number of these teeth is then increased from twelve to twenty-four so that the flux set up in each tooth is appreciably smaller.

Mr. Roth's observations about self-excitation have interested me very much. In German power houses it is now required that large polyphase generators shall be able to carry as leading load 80 per cent of their rating. This requirement has a close relation to the problem of self-excitation discussed by Mr. Roth. This problem will be of even more importance in the future if the lengths and voltages of transmission lines are increased.

In conclusion I should like to briefly mention that the principal progress which has been made in the development of

large turbo generators has been due to the avoidance of stray losses. These stray losses were due to (1) current distortion in the slot copper; (2) flux passing parallel to the slot sides and of too high tooth saturation; (3) flux passing from the field into the open slot; (4) variations in flux density around the circumference of the field, due to the slot openings; (5) the leakage flux from the end windings, (a) in the copper of the end windings, (b) in the end clamping parts (6) iron short circuits due to bad workmanship in slotting and assembling the cores.

From this paper of Mr. Roth's and from his previous publications it is very evident that the author has dedicated much study and research to the problem of decreasing the stray losses and of their exact measurement.

J. Rosen (communicated after adjournment): I would refer only to one section of Mr. Roth's paper in which he deals with the difficulty of alternator instability. It is sometimes forgotten that many of the difficulties lie in the excitation circuit. Some ten years ago, instability was experienced on an 18,000-kv-a. alternator, operating at unity power factor and sometimes with a leading power factor. The alternator air-gap was increased with entirely satisfactory results.

Later experience and tests on other plants showed that attention should also have been directed to the design of the exciter. One of the improvements adopted was the addition of a few series turns to the exciters which overcame entirely the alternator instability difficulties which had up to that time been experienced. The tests have proved that sudden changes in load, faulty synchronising, and faults in the transmission line are reflected in the alternator rotor by momentary increases in the value of the rotor current. I would refer to the papers, and the discussions upon them, on "Exciter Instability" by R. E. Doherty[3], and "Some Problems In High-Speed Alternators and their Solution"[4] by the writer, in which the whole problem is discussed in full.

Calculated figures are given by Mr. Roth of the total inherent reactance of the plant. It would be of interest to learn if they are confirmed by actual sudden-short-circuit tests at the normal operating voltage.

E. Roth: The most important observation presented in this discussion has been expressed by Messrs. W. F. Dawson, Philip Torchio, C. M. Laffoon, E. H. Freiburghouse, and W. B. Kirke, and regards the armature reaction to which American practise gives lower values than that which exists in our alternators.

Mr. Laffoon has given a very complete statement of this point and I am in general in agreement with him. His comments apply more particularly to the conditions of stability.

These machines were designed to run first at $41^2/_3$ cycles in parallel with the distributing system of Paris, and later at 50 cycles. In fact, the machines have never been operated at $41\,^2/_3$ cycles. Moreover the customer wanted a very low value of instantaneous short-circuit current, of about four times the normal current, which condition had never been required before from large turbo alternators. It was therefore necessary to design a machine in accordance with these requirements without neglecting, of course, the condition of stability.

Four years' experience has shown that these machines have been giving entire satisfaction to the users. Had difficulties arisen with regard to stability, it would have been easy to enlarge the air-gap of these machines sufficiently without exceeding the standard American temperature rise of 90 deg. cent., which up to the present has never been attained in our machines.

These machines have been designed for 35,000 kw. at 80 per cent power-factor, that is, 43,750 kv-a.; in fact, they are operated at 40,000 kw. and 50,000 to 55,000 kv-a.

Based upon this experience the 60,000-kv-a. machines have been built on the same principles but the flux has been increased slightly and the air-gap enlarged to maintain the same conditions of stability. Considering the operating conditions we are confident that they will run as satisfactorily as the former, and should difficulties arise these could be easily remedied.

As pointed out by Messrs. Torchio, Kirke, and Pohl, the low value of the instantaneous short-circuit current could have been obtained by reactance coils. This solution was examined very seriously but had to be rejected. Indeed, these reactance coils are very cumbersome, and the price of the alternator together with reactance coils has been found higher than that of the alternator with leakage slots alone. The efficiency using reactance coils is less than with the solution adopted; first, it is not possible to build reactance coils with a loss smaller than 0.15 to 0.20 per cent, and further, when external reactance coils are used the alternator has to be operated at a higher terminal voltage, which creates core losses which do not exist in the case of leakage slots.

With regard to operation, the use of reactance coils or of leakage slots leads exactly to the same result. Whenever it is desired that the voltage drop at the busses on short-circuit be not too high, individual reactance coils should be installed on every feeder.

I wish to emphasize what I have already stated in my paper, that using leakage slots in a given machine does not practically alter the conditions of stability; thus should a customer require from American manufacturers as small an instantaneous short-circuit current as in the Gennevillier's machines, they could obtain it, without changing any of the properties of their machines, by simply adding leakage slots.

I greatly appreciate the technical progress which the American manufacturers have made by designing their 62,500-kv-a. turbo alternator for 1800 r. p. m. I know very well the difficulties which they may have encountered and I think that this is a still more marked progress than that which the Socéité Alsacienne made when they built their 45,000-kv-a. alternators for 1500 rev. per min., which capacity was at that time only realized at 1200 and 1000 rev. per min. I have learned with great interest that Mr. Laffoon sees the possibility of constructing 75,000-kw. machines at 90 per cent power-factor and 1800 rev. per min. In Europe we think that it is possible to build 50-cycle turbo alternators for over 100,000 kv-a. at 1500 rev. per min. and for 40,000 kv-a. at 3000 rev. per min.

Hydrogen as a Cooling Medium for Electrical Machinery

BY EDGAR KNOWLTON[1] CHESTER W. RICE[1] E. H. FREIBURGHOUSE[1]

Members, A. I. E. E.

Synopsis.—*This paper presents the results of a large amount of theoretical study and a large number of tests to determine the advantages of hydrogen as a cooling medium in electrical machiney.*

The conclusions fall into two classes, some definite and some speculative. In the former class are:

1. For the same operating temperature a steam turbine-driven generator of a given size will have a capacity at least 30 per cent greater when operated in hydrogen than when operated in air.

2. The efficiency will be 1 per cent or more higher.

3. There will be no danger of fire destroying the insulation.

4. The detrimental effects of corona if present will be greatly reduced.

5. The machine may be protected by suitable devices from the formation of an explosive mixture of hydrogen and air.

6. The frame can be made sufficiently strong to resist an explosion. This is additional security in case of failure of the protective devices or negligence in operation.

7. The cooler for removing the heat from the hydrogen may be considerably smaller than a cooler for removing heat from air.

In the speculative class are:

1. A hydrogen pressure of several atmospheres will result in still greater possibilities provided a sufficiently gas tight enclosure can be developed.

2. The insulation may be made thinner and still have as long a life as the present insulations operated in air.

I. Introduction

SEVERAL years ago, Dr. W. R. Whitney suggested in a note to one of the writers the desirability of studying the problem of using hydrogen as a cooling medium for large electrical machinery. He pointed out that it is purely an accident that our machines are operated in air and that an atmosphere of hydrogen was much more favorable for the following reasons:

1. Less windage loss, because of the low density of hydrogen.

2. Cooler, because of high heat conductivity of hydrogen.

3. Less damage due to electrical failure, because the insulation cannot burn.

This suggestion of Dr. Whitney led to an extensive study of the characteristics of hydrogen and other gases as cooling media.[2,3,4] An investigation of the windage losses has also been reported.[5] A subsequent investigation showed that the idea of using hydrogen as a cooling medium in electrical machinery was proposed some years earlier by Max Schuler.[6]

The most desirable application of hydrogen as a cooling medium is to machines having both a relatively large windage loss and adverse cooling factors. These occur in all steam turbine-driven alternators, especially those which at present seem to be approaching the maximum desirable capacity for a given speed. The use of hydrogen as a cooling medium will in such cases allow a greater capacity for a given speed and obviate the necessity, for certain capacities, of reducing the speed or changing to methods of ventilating that are less favorably considered. For example, for an air-cooled machine of a given capacity and speed, it may be necessary to use external blowers for circulating the air, whereas if the same capacity of machine was cooled by hydrogen the fans could be placed on the rotor.

In certain cases of air-cooled machines, with fans mounted on the rotor, the power to drive the fans becomes excessive if the fans are designed to circulate the maximum quantity of air which can be obtained with the diameter and speeds chosen. It is customary in such cases to be content with a lesser quantity of air than is otherwise desirable. With a hydrogen-cooled machine a 25 or even a 50 per cent increase in power to drive the fans is of no relative importance.

II. Characteristics of Hydrogen

The important characteristics of hydrogen when compared with air as a cooling medium for large high speed electrical machines are:

A. Lower density
B. Higher thermal conductivity
C. Higher forced heat convection
D. Practically no damage to insulation by corona
E. Prevention of fire

A. Lower Density. Tests in hydrogen showed a windage loss of 10 per cent of that in air which agrees with the chemical analysis of commercial hydrogen. The total losses of large capacity alternators of 1800 or 3600 rev. per min. amount to approximately 2½ per cent and the windage loss is one or more per cent of the rated capacity. By operating such a machine in hydrogen the windage loss is practically eliminated and results in about 1 per cent increase in efficiency.

B. High Thermal Conductivity of Hydrogen. Hydrogen has approximately seven times the heat conductivity of air or as high a thermal conductivity as the

ordinary insulating materials. When a machine is operated in air any spaces in the insulation, or between the insulation and slot sides, appreciably increases the thermal drop from the copper to the surface from which the heat is to be removed by the air. With hydrogen in the machine, the gas spaces are no longer harmful in this respect because of the greater heat conductivity of the hydrogen. To illustrate the effect, consider an extreme case in which the armature insulation is 7/32 in. thick and the spaces aggregate 1/64 in. additional. The following table gives the thermal drops in both cases with an energy flow of 0.32 watts per square inch through the insulation, assuming a thermal resistance of 270 deg. cent. which is closely true for the type of insulation considered.

	Air	H_2
Drop through insulation	17.5 deg. cent.	17.5 deg. cent.
Drop through gas spaces	9.	1.25
Drop, total	26.5 deg. cent.	18.75 deg. cent.

An additional gain will be made in the thermal drop in those heat paths in the armature core and teeth which are parallel to the axis of the armature, since the spaces between the laminations will be filled with hydrogen. The ratio of the temperature drop in a hydrogen atmosphere to that in air would be about 65 per cent in this case.

C. Forced Heat Convection. The efficiency of heat removal by high velocity gas blowing over the surfaces is approximately 1.3 times as great in commercial hydrogen as in air. In other words, the surface film temperature drop required in the hydrogen machine to transfer one watt per sq. in. is 77 per cent of that required for the same machine in air.

The machine under consideration is totally enclosed, and the heat is removed from the circulating air, or hydrogen, by tube and fin surface coolers, provided with water circulation. The rate of heat transfer from hydrogen to a single tube in commercial hydrogen at the usual velocities is approximately three times as great as for the same tube in air at the same velocity. Somewhat the same ratio is expected in the case of built-up coolers, since the spacing between the tubes will be large compared with the film thickness, and the mutual influence of the tubes should be small. Accurate tests are, of course, needed to determine the exact ratio.

Effects of Lower Density and Greater Conduction and Convection. We may summarize the temperature conditions for the machine in hydrogen and air as follows:

1. The practicable absence of windage loss when hydrogen is used results in less heat to be removed from the machine.

2. The temperature drop required to transmit a given amount of heat from the copper to the iron, through the insulation, will be materially lower in hydrogen. The temperature drop required to transmit heat across the laminations will also be lower in hydrogen than in air.

3. The temperature drop required to transmit the heat from the surface to the high velocity ventilating gas will be less in hydrogen than in air.

4. When the gas reaches the cooler, less temperature difference will be required to remove the heat from hydrogen than from air, and, therefore, the hydrogen will be cooler when it returns to the machine.

The accumulative effect of all these factors is considerably lower copper and insulation temperatures, and the advantage may be used either to increase the life or the capacity of the machine as seems most desirable.

D. Corona in Air and Hydrogen. The potential gradient at which corona starts in hydrogen is approximately 60 per cent of that at which it starts in air.[7] Thus a machine designed to operate in air without corona might produce severe corona when operated in hydrogen at atmospheric pressure. The destructive nature of corona in air on insulation is well known and it was, therefore, feared that insulation troubles would soon develop, if a standard machine without corona shields were operated in hydrogen. To test this point some preliminary comparative endurance tests were made in hydrogen and air on two similar samples of yellow varnished cloth. These samples were made by winding the cloth around glass tubes approximately ¾ in. in diameter by 7 in. long, until thirteen layers were obtained. The inner electrode consisted of a ½ in. diameter copper tube which was slipped inside of the glass tube, and the outer electrode consisted of several widely spaced turns of 0.01 in. diameter cotton covered wire extending over approximately 1 in. of the central portion of the cloth. One sample was contained in a glass bell jar through which hydrogen at atmospheric pressure was slowly circulated, and the other was placed in the open air. The samples were connected in parallel across the terminals of a small testing transformer, and the voltage gradually raised. The tests were made in a moderately darkened room, and it was expected that corona would first be distinctly visible on the hydrogen sample, but this was not the case. On the contrary, needlelike purple streamers were first seen on the air sample. The corona in hydrogen was a very faint diffused glow. Probably in a completely darkened room the corona would have been visible in hydrogen before it appeared in air. The main point of interest was the strikingly different appearance of the corona in the two gases. In air there were vicious needlelike streamers coming out from spots along the wires, while in hydrogen the appearance of corona was soft and diffuse in character, and gave the impression that hydrogen corona would be harmless compared with air corona on the same sample and at the same voltage. A potential difference of

Jensen, *Phy. Rev.*, Vol. 8, p. 433, 1916.

10 kv. at 60 cycles was applied for 76 hours. Fig. 1 shows the samples with the fine wire removed. In the air sample small holes may be seen along the imprint of the wire on the cloth. Photographs were taken of the samples when unrolled, but the variations in light reflections completely masked the effects of corona; therefore a contact print was made and this was photographed to obtain Fig. 2. The samples of cloth were about three feet long, and since a reduction to the size necessary for reproduction would render the punctures invisible, only the outer and inner layers are shown in this figure. These layers are numbered 1 and 13 respectively, No. 1 being the surface on which the wire was wound, and No. 13 the layer which was against the glass tube. In both cases the intervening layers resembled to a degree those shown.

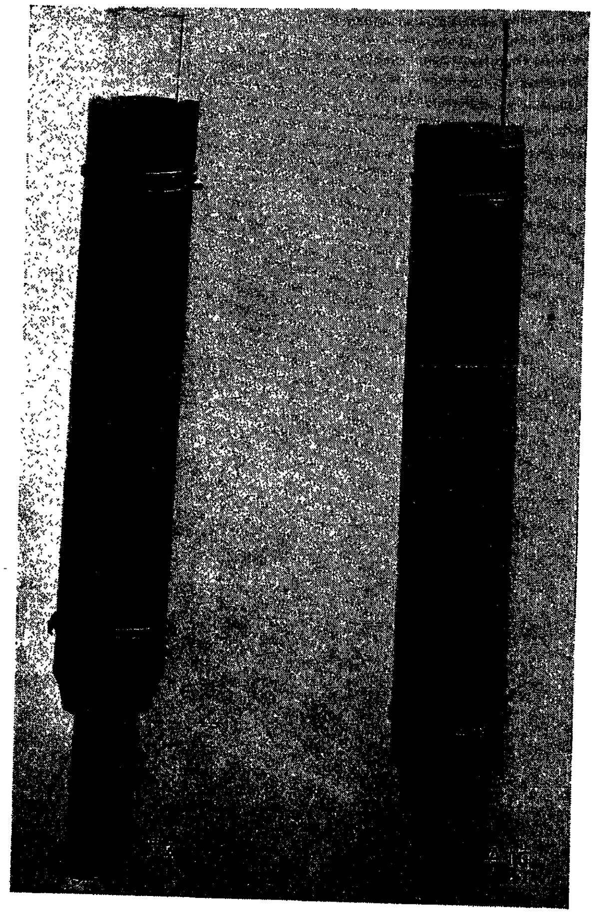

Fig. 1—Samples of Varnished Cloth Subjected to Corona in Air and Hydrogen

The sample in air was punctured through thirteen layers as shown in the figure. The hydrogen sample had no punctures. The only noticeable effect was the removal of the glaze on the varnished surface in the vicinity of the wire. This duller area was greatest on the outer layer, but was present on all layers. On the outer layer this removal of glaze extended over a considerably greater area in the hydrogen than in the air sample.

Different materials were tested in a similar manner for 56 hours. The damage in each case was not so great, but the same relative effects were obtained.

The appearance of corona in hydrogen resembles the appearance of corona in air at reduced pressure. It was, therefore, interesting to compare the relative destructiveness of corona in air at atmospheric pressure with that in air at reduced pressure. Some preliminary tests in air at one atmosphere and one-half atmosphere pressure indicate that the corona is not materially different in the two cases. In order to obtain more information on the question of whether corona destruction is due to mechanical or chemical effects, six layers of yellow varnished cloth were placed on a table and a drop of concentrated nitric acid placed in the center, with five drops of dilute acid surrounding it. An inverted beaker was placed over the drops to retain the acid fumes in contact with the cloth. After three days a visual inspection of the samples showed no difference between the part exposed to the acid fumes under the beaker and the portion exposed to the air. There was, however, a very marked reduction in mechanical strength in the area subjected to the acid fumes. A pencil point could be easily forced through all six layers anywhere within the beaker diameter,

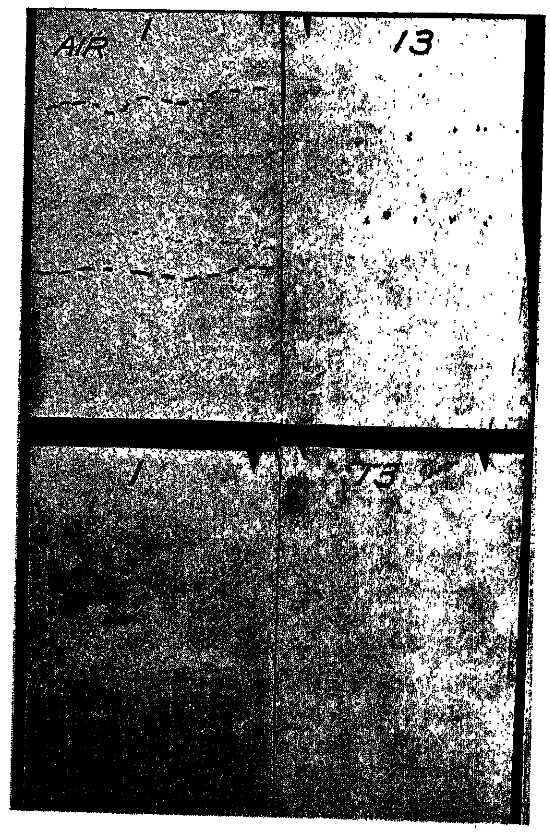

Fig. 2—Effect of Corona on Varnished Cloth in Air and Hydrogen

Two upper samples in air. Two lower samples in hydrogen. In both cases No. 1 was the surface on which wire was wound and 13 was the surface which was against the glass tube.

whereas outside of the beaker diameter the material retained its normal strength.

It may be inferred from these tests that the destructive action of air corona on insulation is due to the mechanical weakening of the insulation by the presence of nitric acid or ozone produced by the corona, followed by erosion of the corroded material by the mechanical or blast action of the corona streamers. In hydrogen, corrosion is not produced, as no chemical action takes place, and erosion is not of itself sufficiently severe to seriously impair the life of the insulation.

Following these preliminary tests, G. B. Shanklin made corona endurance tests on eight samples of armature insulation. Four were varnished cloth and four mica tape insulation, each having a thickness of 0.23 in. Horn fibre 0.015 in. thick was moulded over the insulations and over this were wound thin copper strips ½ in. wide with a similar space between the edges. Half of the samples were placed in hydrogen at atmospheric pressure and half in air and subjected to a potential of 22,000 volts which was sufficient to produce clearly visible corona at the edges of the copper strips, in a slightly darkened room.

The two cloth samples in air failed after 2500 and 2650 hours operation. The remaining samples were tested for 8000 hours without failure.

there have been cases of fire starting on the surfaces of insulation without any electrical failure. If ventilated with air, the fire may spread with great rapidity

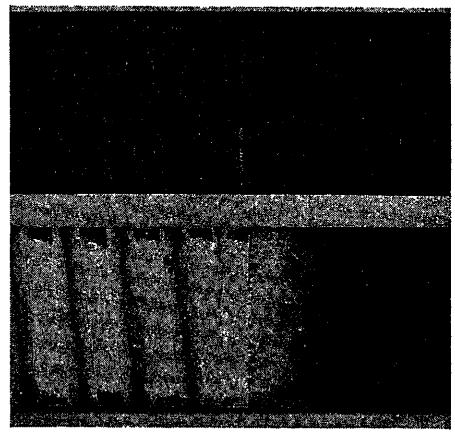

Fig. 3—Appearance of Armature Coil Insulation Subjected to Corona Endurance Tests in Air and Hydrogen

and injure the winding to the extent of requiring extensive replacement. Also, a slight electrical failure, involving initially one or two coils, may start an equally serious fire. With hydrogen no fire can occur and the

TABLE 1
RESULTS OF THE OPERATION OF ARMATURE INSULATION IN AIR AND HYDROGEN

	Mica Tape in		Cloth Tape in	
	Air	H_2	Air	H_2
	No failure		Failed	No failure
Length of Test in Hours.......	8000	8000	2500 2650	8000
Appearance See Fig. 3 with copper strip removed	Fibre bleached. Pitted through fibre and next layer of cloth tape.	Fibre retained original color. Fibre pitted only in a few places.	Fibre partly bleached. Pitted through fibre and two layers of cloth in quite a number of places.	Fibre slightly bleached. Pitted through fibre and through two layers of cloth in a few places.
Dielectric strength test. Test started at 30,000 and increased 3000 volts each minute	60,000	63,000	31,500	48,800

Table I gives a condensed statement of the results.

None of the mica tape samples showed any pitting of the mica tape. The horn fiber covering was entirely pitted through in numerous places in the air sample but examination of the mica tape disclosed no pitting. Dissecting the insulation revealed brown powder and white powder in some places between the layers of tape of the air sample but none in the hydrogen sample. Fig. 3 shows the appearance of the mica tape samples.

A visible examination of the cloth samples would not lead one to suppose that there should be so great a difference in puncture values as shown by the tests. It seems reasonable to conclude that the cloth in air was injured considerably more than the cloth in hydrogen but not to the extent indicated by the puncture values since unknown factors may also have considerable influence on puncture values.

E. Prevention of Fire. In steam turbine generators

damage due to an electrical failure will be confined to a few coils.

Most of the large capacity air-cooled steam turbine generators are provided with pipes for the injection of steam or water in case of fire. The pipes are usually located near the ends of the windings and when the steam or water is turned on the ends of the windings are enveloped or covered by the extinguishing substance as the case may be. When there is a suspicion of a fire, the operator naturally wishes to be sure that the situation is serious before a machine is taken off the line and subjected to steam or water, and the tendency is to wait so long that damage may be done either by the fire or by the amount of steam or water that is turned into the machine. With a hydrogen filled machine no such disturbing condition can exist. The only failure to be considered is an electrical short circuit or ground, and the well known automatic devices now

available should remove the machine from the line before any serious damage results.

III. Influence of Hydrogen on the Design of Insulation

A few tests were made on the puncture voltages of sheet insulating material in air and hydrogen and no appreciable difference was found in the two cases; therefore no conclusion could be reached.

In order to obtain some information on the effect of hydrogen on the life of fibrous insulation, three samples of black varnish cloth were tested for 1300 hours under the conditions given below. The effect on the flexibility is given in the last column

Sample Number	Surrounding Medium	Temperature	Flexibility
1	H_2	100 deg. cent.	100
2	Air	100 deg. cent.	25
3	Air	25 deg. cent.	90

The samples were in the form of strips supported so that the air or hydrogen had free access to both sides. This condition is much more severe than that existing in insulation wound tightly on a coil and protected by external coverings of varnish, but it gives results of value in forming conclusions as to the relative merits of the two gases in respect to the flexibility of the insulation. These tests of samples at about operating temperatures indicate that the life of insulation will be greater in hydrogen than in air as far as this life depends on brittleness of insulation.

The thickness of armature insulation for higher voltages is at present governed by the consideration of having a potential gradient that will not cause corona in minute spaces which may be present initially or developed later in the internal parts of the insulating material. The thickness necessary to withstand mechanical injury, high-potential tests, and the stresses of operation, is less than that required for the above consideration, and the removal of the more severe requirement first mentioned will allow a favorable decrease in thickness with the attendant benefits in design.

The thickness of field insulation is governed largely by the mechanical requirements of operation, but mechanical deterioration depends to a great extent on oxidation, and since this is not present in hydrogen, an increase in life may be confidently expected.

IV. Selection of the Most Suitable Hydrogen Pressure

If we neglect the question of leakage it surely would be a strange coincidence if it should be found that the most efficient pressure for hydrogen operation is at that of our surrounding atmosphere. To illustrate the properties which may be obtained in hydrogen under pressure, consider the case of ten atmospheres, or 147 lb. per sq. in. absolute.

1. The windage loss will be equal to that of the same machine in air.

2. The heat conductivity of a gas is independent of the pressure, and will therefore be the same as hydrogen at atmospheric pressure, which, as has been stated, is seven times as great as air.

3. The forced heat convection, or efficiency of heat removal by the high velocity gas flowing over the surface, will be approximately thirteen times as great as for the air machine. This condition would render the surface temperature drops negligible, whereas in the air filled machine, the surface drops are considerable.

4. The dielectric strength of hydrogen, for one-cm. spacing at ten atmospheres pressure, will be approximately 60 per cent as strong as transil oil in bulk.

Thus a machine running in hydrogen at ten atmospheres pressure would approach many of the properties of an oil immersed machine and still have the same windage loss as an air cooled machine.

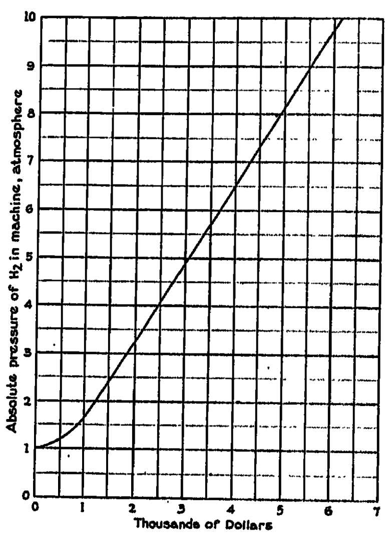

Fig. 4—Yearly Cost of Hydrogen Leakage per Pin Hole as a Function of Hydrogen Pressure

Fig. 4 shows the yearly cost of hydrogen leakage per pin hole of 0.025-cm. diameter (0.0005 sq. cm. area) as a function of the pressure of hydrogen in the machine. It will be noted that below a pressure of 1.9 atmospheres the curve is of a parabolic form and above that pressure it is a straight line. This difference is on account of the fact that the efflux of a gas is in conformity with one law up to a certain pressure and above that pressure it is in accordance with a different law, the point of transition being where the lower or outside pressure is 52.7 per cent of the higher pressure from which the gas escapes. At this point the velocity in the escaping jet is equal to the velocity of sound in the gas at atmospheric pressure and density or

$$V = \sqrt{\frac{\gamma P_0}{\rho}}$$

Where

V = velocity in cm. per sec.

γ = ratio of specific heat at constant pressure to that at constant volume

ρ = density of H_2 at the lower pressure in grams per c. c.

P_0 = External pressure in dynes per sq. cm. One atmosphere equals 1.0132×10^6 dynes per sq. cm.

At any pressure below 1.9 atmospheres, the transition point when the lower pressure is assumed to be one atmosphere, the amount of hydrogen passing through the orifice may be calculated from the following equation

$$W = 2.62\, A \sqrt{P\,\rho}\; \sqrt{\left(\frac{P_0}{P}\right)^{1.42} - \left(\frac{P_0}{P}\right)^{1.71}}$$

Where

W = gr. per sec.

A = area of orifice in sq. cm.

P = pressure of H_2 in machine in dynes per sq. cm.

ρ = density of H_2 in machine in gr. per c. c.

P_0 = external pressure in dynes per sq. cm.

For pressures above the point of transition the expression

$$W = 0.685\, A \sqrt{P\,\rho}$$

should be used.

In making calculations for the curve the area of the orifice was assumed to be as stated above, and the cost of hydrogen \$6.00 per kilogram, or approximately \$0.015 per cu. ft.

Derivations of the above equations are given by Lamb[8]. The determination of the most efficient pressure will depend on many design factors which are now unknown and therefore an estimate of the most suitable pressure, all things being considered, is impossible at the present time.

V. Tests of a Hydrogen Filled Machine

Object. Tests were made with a steam turbine type alternator operated as a synchronous motor to determine the capabilities of hydrogen as a cooling medium in a closed system of ventilation.

During the tests attention was directed primarily to the operating characteristics of the alternator which are inherent to the density, thermal conductivity, and convection of hydrogen. To emphasize these characteristics comparisons were obtained by making similar tests with air as a cooling agent.

While making these tests an opportunity was given to apply and observe the operation of protective devices, also to study some of the difficulties pertaining to the confinement of hydrogen under moderate pressures.

Description of Generator. A high-speed marine type alternator was selected for these tests, since it had fairly high windage losses, also because the outer shields which carried the armature were cast integral with the bearing supports, thus making a short closed circuit system of ventilation readily obtainable.

Ventilation System for Tests. Fig. 5 is a view of this generator arranged with closed circuit ventilating ducts and coolers for removing the losses. The gas was discharged from the top of the stator frame into a sheet iron chamber which was attached by gas tight joints to the discharge flange of the stator frame. The gas then divided and each half passed through two coolers located near each end of the chamber from which the heat was removed by water. After passing through the coolers, the gas was drawn downward from the ends of the chamber through diverging sheet iron ducts over each end of the stator frame, thence into the generator through the fans on each end of the rotor.

Coolers and Rate of Heat Transmission. Since it was the purpose of these tests to determine the relative temperature rises of the windings above that of the incoming cooling medium, little attention was given to the coolers other than to hold the water flow fairly constant.

The area of the cooling surface was 400 sq. ft., and the

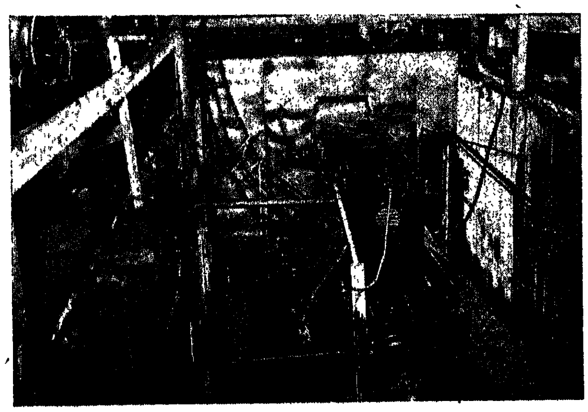

Fig. 5—Turbine Generator Arranged for Operation as a Synchronous Motor with Closed Circuit System of Ventilation Containing Hydrogen or Air as a Cooling Medium

net area of the air passages was 4 sq. ft. The velocity of water in the cooler tubes was 25, and the velocity of gas was 2100 ft. per min. Twenty-five gallons of water and 8400 cu. ft. of air were circulated per minute.

Although no accurate heat transfer tests were made on the coolers during operation it was found that they were much more effective with hydrogen than with air.

Protective Devices. Mechanical and electrical devices were used to detect explosive mixtures, automatically eliminate them, and prevent high pressures in case explosions should occur.

A small gasometer was connected to the point of lowest pressure in the machine, thereby maintaining a constant pressure slightly above that of the atmosphere, independent of temperature changes and leakage. Although leakage occurred on account of the crude joints between sheet iron and rough castings, the de-

8. Horace Lamb, Hydrodynamics, Cambridge University Press, 3rd. Edition, p. 23, 1906.

sired pressure was automatically maintained and contamination by air was prevented.

A recording device developed by C. Dansizen gave an accurate continuous log of the amount of impurity in the hydrogen. This device produced a graphic record of the difference in potential between the terminals of a pure metal filament placed inside the generator and through which a constant electrical current was automatically maintained. The resistance of the filament is a function of its temperature which depends upon the rate of heat transmission from the wire to the gaseous mixture, which, in turn, depends on the amount of impurity in the gas. With this apparatus a potential drop of 11.5 volts was observed with pure hydrogen and 12.5 volts with a mixture of hydrogen and one per cent of air impurity by volume.

Another safety device consisted of a metal filament, mounted upon a suitable support, placed within the generator and maintained at a temperature of from 700 deg. to 900 deg. cent. by means of an electric current. A mixture of air and hydrogen, having less than 15 per cent of air, will combine without explosion when brought in contact with the filament. The object of this device was to keep the air constantly being burned out of the hydrogen so that an explosive mixture could never be reached even though air should be continuously leaking into the machine.

Six diaphragms of varnished horn fiber ten inches in diameter and 15 mils thick were inserted in the outer walls of the ventilating ducts to relieve the pressure in case the other devices were ignored or prevented from functioning and an explosion occurred.

Two diaphragms were so located that the gas impinged directly on their inner surfaces. It was feared that the varying force of the gas would cause sufficient movement of the diaphragms to produce failure if these were made of fiber. Lead diaphragms were used in these locations and they were cut nearly through their thickness so that their strength compared favorably with those made of fiber. The inertia of the lead prevented any destructive flutter.

Test Results. A duplicate machine had been operated in air at a load of 3380 kv-a. and at 3000 rev. per min. The losses under these conditions were

	Kw.	Per cent of Output	Per cent of Total Losses
Windage	35	1.48	38
Open Circuit Core Loss	27.5	1.16	30
$I_2 R$	13.25	.56	15
$I_2 R$ Loss of Rotor	16.1	.68	17
Total	91.85	3.88	100

From this tabulation of losses it is seen that a loss of 1.48 per cent of the capacity of the generator is produced by windage. It may be said in general that the windage loss in large steam turbine generators will fall between 1.00 and 1.75 per cent of the full-load capacity.

Unfortunately, conditions made it necessary to run the heating tests at 2400 instead of 3000 revolutions per minute; hence the windage loss was only 51 per cent of normal. This should be kept in mind when considering the results of the tests.

Heating Tests Using Air and Hydrogen for Cooling Agents. Four tests were made, the results of which are shown by Table II. These tests were made at no

TABLE 2

RESULTS OF TESTS WITH AIR AND HYDROGEN AS THE COOLING MEDIUM

Core loss kw	19.	19.	19.	19.
Windage, kw	17.9	1.8	1.8	17.9
Total loss in motor kw	67.7	65.8	47.7	60.7
Temperature rise of rotor winding above average temperature of the ingoing cooling gas	79.	79.2	55.	62.
Maximum temp. rise of armature winding above average ingoing gas	39.	42.5	27.	31.1
Average temperature rise of six temp. detectors between coils of armature winding	35.9	28.2	23.9	28.7
Pressure of gas on suction side of fan inches of H_2O above atmosphere	—	1.	1.3	2.4
Temp. rise of field in deg. cent. per kw. of loss	3.79	3.10	3.23	3.49

load, using the alternator as a synchronous motor, with a value of field current to obtain the desired kv-a. input. Two of the tests, No. 1 and No. 3, were taken with 2400 kv-a. input, to determine the relative temperature rises of the rotor and stator windings using air and hydrogen.

Test 4 was made to determine approximately the reduced load necessary to secure the same temperature rise with air as was obtained with hydrogen in Test 3. Being unable to predict the temperature rises which would exist at the end of the run, the final temperatures in Test 4 were somewhat higher than in Test 3. By a comparison of runs No. 1 and No. 2 it will be seen that one-third more kv-a. were carried on the motor, with the same rise in temperature of the field winding, by using hydrogen instead of air as the cooling medium. The maximum temperature rise of the stator winding, as determined by resistance temperature detectors located between the top and bottom armature coils, was only 3.5 deg. cent. higher during the hydrogen run at 3200 kv-a. than with air during the 2400-kv-a. run.

Comparing tests No. 3 and No. 4, the final temperature rise of the field winding was 62 deg. cent., with air as the cooling agent during Test No. 4 at 2107 kv-a., whereas the rise obtained by Test No. 3 at 2400 kv-a. with hydrogen was only 55 deg. cent. Based upon the data secured during Tests No. 3 and No. 4, it is estimated that a load of closely 2700 kv-a. could have been carried when using hydrogen cooling with an

average temperature rise in the field winding of 62 deg. cent. This is 1.28 times the load of 2107 kv-a. carried when air was used as the cooling agent. It is doubtful whether the temperature rise of the armature at 2700 kv-a. cooled by hydrogen would be more than 1 deg. or 2 deg. higher than the rise obtained at 2107 kv-a. when cooled by air.

The estimates of additional loads of 33 per cent and 28 per cent which have been made would be greater if the tests had been made at the normal speed of 3000 instead of 2400 rev. per min.

VI. Heat Transfer from Rotor Winding

Having determined the increased cooling and rating permissible by the use of hydrogen in the small turbine-driven generator, an estimate was desired of the relative temperature rises which would be obtained by the embedded rotor copper in a large steam turbine-driven alternator.

The temperature drops at heated surfaces cooled by forced convection of air and hydrogen were known, but no information was available by which an estimate could be made of the relative thermal drops from copper

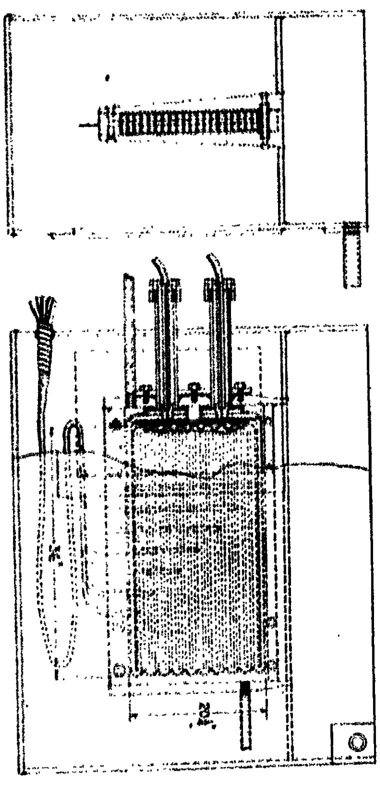

Fig. 6—Simulated Field Coil Arranged for Testing in Air and Hydrogen

through the insulation to the sides of the rotor slots.

To obtain this information, a coil having a resistance of 0.002 ohms at 25 deg. cent. was made of copper strip 0.875 in. by 0.03 in. in section, folded back and forth to obtain 20 layers in depth. The turns were separated from each other by layers of mica, and insulating armor 0.1 in. thick was moulded about the coil. This coil was actual size as regards the cross section but of course its length and shape differed from that of the coil which it represented.

The coil was enclosed in a retainer and seven thermocouples were soldered into the strips of the coil at different depths. The thermocouple leads were carried down through the coil and out of sealed holes in the steel bar at the bottom of the slot; see Fig. 6. As shown by the longitudinal and transverse sections, the coil container was welded into and hung from the edges of a

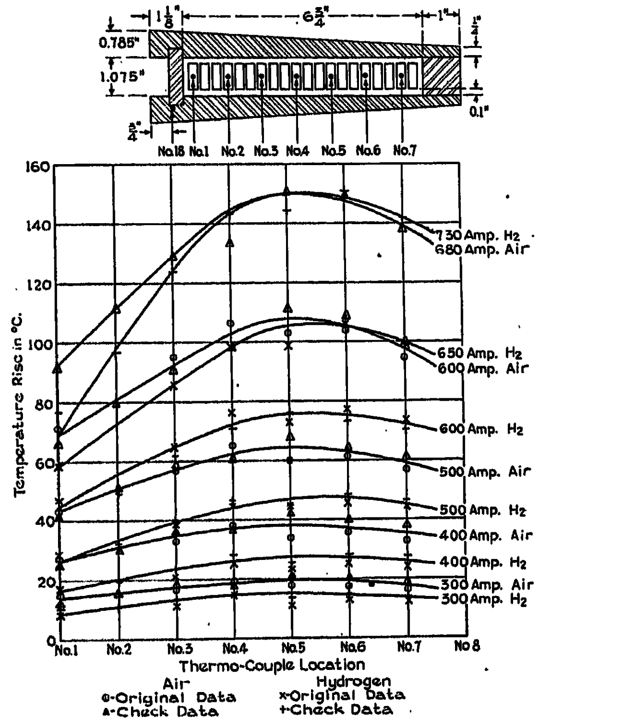

Fig. 7—Temperature Rise of Different Layers of Simulated Field Coil above Temperature at Location No. 18, when Cooled by Air and by Hydrogen

rectangular slot in a steel plate. The coil, its container, and supporting plate were mounted in a steel box. Below the supporting plate the space about the container was lightly packed with silox, a silicon oxygen carbon compound of very low thermal conductivity. This caused practically all of the heat to pass to those surfaces of the container which corresponded to the surfaces exposed at the air gap of an actual machine. The heat was removed from these surfaces by water. The gas used for impregnating the coil was admitted and discharged through the end plates of the container. Gas pressure was maintained constant at 3¼ in. of water by means of a gasometer. The hydrogen used in these tests was analyzed and found to have the following composition by volume:

Carbon dioxide	0.4
Ethylene	Nil
Oxygene	1.0
Carbon Monoxide	0.2
Hydrogen	90.5
Methane	Nil
Nitrogen	7.9
	100.0

The gas used in this test did not contain as high a percentage of hydrogen as is present in the average commercial hydrogen.

Thermometers were placed in the water in contact with the face of the teeth and on the water-cooled

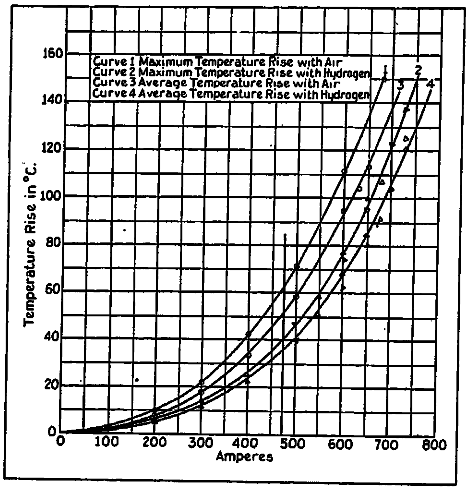

FIG. 8—TEMPERATURE RISE OF SIMULATED FIELD COIL WHEN COOLED BY AIR AND HYDROGEN

surface of the slot wedge. Three thermocouples were soldered to the bottom of ⅛-in. holes which were drilled ¾ in. below the water-cooled surface of the teeth. Their leads were protected from the water by small copper tubes soldered into the drilled holes.

The temperature rises were taken by resistance of the

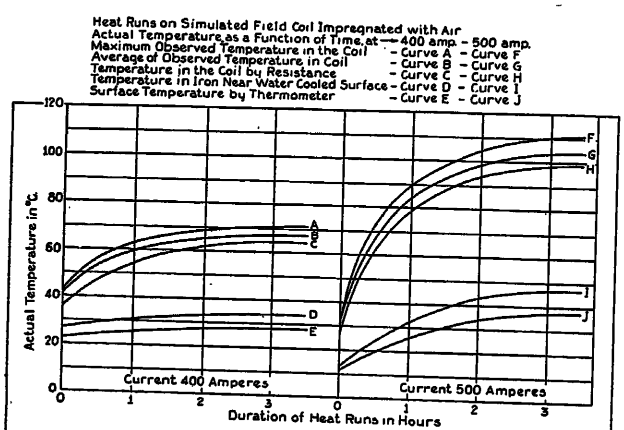

FIG. 9—RECORD OF TESTS ON SIMULATED FIELD COIL IN AIR WITH CURRENTS OF 400 AND 500 AMPERES

coil itself, and by the thermocouples in the turns of the coil. In Fig. 7 the temperature rises of the thermocouples are plotted above the temperature of No. 18 thermocouple which was embedded near the face of the tooth. From an inspection of temperatures plotted in this figure it will be seen that the bottom strips of the coil did not attain the highest temperatures. Sixteen heat runs were made at different values of current, the maximum being 730 amperes, with coil impregnated with hydrogen.

The final maximum and average temperature rises, above that of the thermocouple embedded in the tooth face, are shown in Fig. 8 as a function of current. With 475 amperes, which is normal exciting current, both the average and maximum temperatures of the

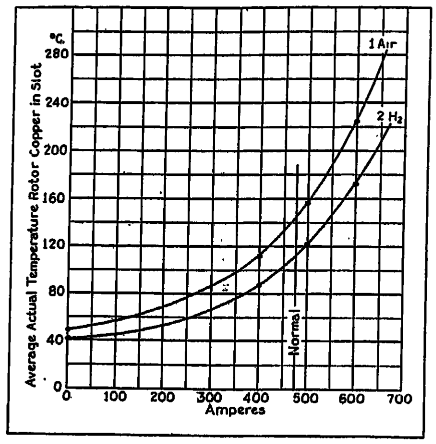

FIG. 10—ESTIMATED ACTUAL TEMPERATURES OF THE FIELD COIL OF A LARGE CAPACITY STEAM TURBINE-DRIVEN GENERATOR WHEN COOLED BY AIR AND HYDROGEN, INCOMING GAS TEMPERATURE ASSUMED TO BE 40 DEG. CENT.

coil were about 35 per cent less with hydrogen than with air.

In Fig. 9 are shown the actual temperatures during

two heat runs at 400 and 500 amperes when the spaces were impregnated with air. Curves *D* and *I* refer to thermocouple No. 18 in Fig. 7. Curves *E* and *J* were

obtained by a thermometer located in the water close to the face of the tooth in which thermocouple No. 18 was placed. Referring to the final temperatures, the difference between D and E and between I and J are 7 deg. and 10 deg. cent. respectively.

Table III gives the final maximum and average temperature rises, watts input, and watts dissipated per square inch of coil surface during a number of the heat runs with the coil impregnated by air and hydrogen.

This data was used to estimate the field temperature rises in air and hydrogen of the machine whose field winding was simulated by the coil tested. See Fig. 10. The temperature of the medium entering the machine was assumed to be 40 deg. cent. It will be noted that at 0 amperes the temperature of the winding was 50 deg. for air and 41 deg. cent. for hydrogen cooling. These are the temperatures which would be attained by the field winding because of windage loss only. It will be seen that the temperature rises above the temperature of the medium entering the machine are 10 deg. and 1 deg., depending on which medium was assumed.

The normal exciting current was 475 amperes. Referring to Fig. 10, Curve *1*, it is seen that, at the current given, an actual temperature of 143 deg. cent. would be obtained in the embedded portion of the rotor body when cooled by air, whereas as shown by Curve *2*, the same load might be carried when cooled by hydrogen at an actual temperature of 110 deg. cent. This is a gain of 23 per cent. The armature temperature would also be reduced in approximately the same ratio.

Capitalized otherwise, the field might be operated at 143 deg. cent. with an excitation of 550 amperes when hydrogen-cooled, which is sufficient to carry a load of 25 per cent more than normal. This does not take into account the lesser temperature drop at the surface of the cooler. With the increased load and reduction in windage loss the efficiency of the machine would be 1.2 per cent higher. These values agree closely with the results of the tests on the 3380-kv-a. machine mentioned in Section V.

VII. Explosions

The question most frequently asked the authors by those interested in this subject is in regard to explosions.[9]

9. A Study of Explosions in Gaseous Mixtures, by Kratz and Rosecrans, *Bulletin* 133, Engineering Experiment Station, University of Illinois.

In order to answer this question some preliminary tests were made by E. W. Kellogg. The apparatus consisted of an iron pipe 4 in. in diameter and 24 in. long, provided with a steam-engine indicator and spark plugs. The following maximum pressure rises were observed:

Gas Mixture by Volume	Maximum pressure lb. per sq. inch gage
20 per cent H_2 in Air	53
30 " " " " "	61
50 " " " " "	54
60 " " " " "	50
65 " " " " "	50

It was impossible to ignite mixtures containing more than about 65 per cent hydrogen. On the basis of heat content, an ideal mixture of hydrogen and air should produce a temperature of 4100 deg. cent. with a pressure of about 180 lb. per sq. inch gage. That such pressures are not obtained in practise is due to dissociation and the cooling effect of the enclosure. To test the effect of an explosion on insulation, small pieces of double cotton covered wire were placed in the bomb. Examination showed the outer layer of cotton to be scorched and slightly weakened. When the pressure was relieved by a paper vent over the end of the bomb, no scorching was detected. It may be concluded from these tests that an explosion in a machine would have no detrimental effect on the insulation. To determine the feasibility of limiting the explosive pressure in a machine to moderate values by the use of suitably placed vents, the model shown in Fig. 11 was constructed. This represented as closely as convenient the various parts of the generator. The parts were full size except that the model was 2 in. thick in a direction normal to the surface of the page.

The various spaces simulated were:

A—fan space
B—space around ends of winding
C—air gap
D—armature core and ducts
E—chamber encircling armature core
F—intake chamber
G—connecting passage from *E* to *F*

Pressures were measured by a steam-engine indicator started automatically just before the ignition of the gas. In general, the thicker the diaphragm the greater was the pressure developed by the explosion. Volumes of air and hydrogen as nearly equal as possible were used, but in spite of the fact that the explosive range is considerably beyond this point in both direc-

TABLE 3
TEMPERATURE DATA ON FIELD COIL

Gas in Coil	H_2	Air	H_2	Air	H_2	Air	H_2	Air	H_2	Air	H_2
Amperes	200	200	400	400	500	500	600	600	650	650	730
Watts input	81.2	82.0	360.0	377.6	612.5	647.5	972.0	1054.8	1200.0	1280.2	1636.0
Watts per sq. in. of coil surface	0.142	0.143	0.626	0.657	1.067	1.128	1.693	1.835	2.090	2.230	2.845
Max. temp. rise above thermocouple in Tooth face	5.9	8.4	25.6	37.9	46.2	64.7	77.3	106.4	100.1	126.1	138.5°C
Average temp. rise above thermocouple in Tooth face	4.6	7.3	22.5	33.4	40.9	57.7	68.7	95.8	85:3	113.2	120.8°C

tions there were several times that the charge failed to explode, doubtless due to incomplete mixing. Twenty-five explosions were made and the highest recorded pressure (45 lb. per sq. in.) occurred when the venting diaphragms were replaced by steel plates.

There is no more reason to fear the explosion of a machine filled with hydrogen than that of other apparatus having considerable stored energy such as boilers, gas tanks, rotating elements, high-speed trains and automobiles, and various other familiar examples. Most of us fear a new condition if it has the possibility of accident, and accept as a matter of course the usual dangers of our daily lives.

VIII. Conclusions

To summarize previous statements, the advantages which may be realized in various proportions are: lower temperatures, greater capacity, lower losses, elimination of fire hazard, longer life, and greater reliability.

There seems to be no great difficulty or danger in the use of hydrogen in a properly designed and operated machine.

The automatic maintenance of hydrogen pressure slightly above atmosphere will prevent the ingress of air and the possibility of the explosive mixtures.

Several devices, each operating on a different principle, may be used to detect a change in the mixture and give an alarm long before the mixture reaches an explosive stage.

Finally, should all of these contrivances fail to operate and a spark be applied to an explosive mixture inside the machine the results would not be serious, since it is not difficult to vent the machine to reduce the force below a destructive value.

Grateful acknowledgment is made to Dr. W. R. Whitney and Dr. H. G. Reist for the keen interest which they have taken in the progress of the work.

Discussion

G. E. Luke: In determining the probable temperature rise of any electric machine, we may first start with the calculation of the volume of fluid necessary to be circulated through the machine in a given time.

Thus, comparing air and hydrogen as possible fluids, the volume of hydrogen required will be only 2 or 3 per cent more for hydrogen than for air, on the basis of the same temperature rise of the gas due to the same loss absorbed. This temperature rise in the gas used should not be over one-half of the maximum temperature rise of the ventilating surfaces.

The ventilating-surface temperature can be calculated when the surface-heat-transfer coefficient (K) is known. Considerable data regarding this constant (K) are available for air[1]. However, little experimental data are published for hydrogen. Some experimental tests by Rice[2] on a small cylinder (axial flow) gave a heat transfer for hydrogen 137 per cent of that for air at an average velocity of 5000 ft. per min. On the other hand Rice[3] gives for large plane surfaces this heat transfer (K) as proportional to $\frac{\rho\, k}{\mu}$, where ρ, k, and μ are the density, thermal conductivity, and viscosity of the gas, respectively. On this basis, the unit heat transfer from the surface will be about the same for hydrogen as for air.

Pohl[4] has calculated from Nusselt's[5] work this coefficient (K) to be about 50 per cent greater for hydrogen than for air. The equation given by Nusselt can be reduced to the form[6] of

$$K \,\alpha\, k^{n-1} \quad (\rho\, C_p\, V)^n$$

where

K = unit surface heat transfer
k = thermal conductivity of the gas
ρ = density of gas
C_p = specific heat of gas
V = velocity of gas

This equation is also practically the same as that given by Pohl. Thus, the ratio of the heat transfer with hydrogen to that obtained with air will depend upon the exponent (n) of the velocity factor. Thus, with (n) = 1, the ratio is about 98 per cent and with n = 0.786 as given by Nusselt the ratio becomes about 150 per cent. The writer has found that for turbulent gas flow where the gas path is straight and uniform, the heat loss varies as $V^{0.85}$ to $V^{0.95}$; and where the air path is irregular the unit heat loss varies as $V^{0.75}$ to $V^{0.85}$. Hence, it is estimated that in an average generator the unit heat dissipated with hydrogen will be about 25 per cent greater than with air, which is not far from the figure given in the paper.

The paper states that the rate of heat transfer in the coolers should be about three times greater for hydrogen than for air. This figure seems too high; it might be correct for the tubular surface but is probably too high or the fin surface, and this latter surface is usually several times greater than the tubular surface. The writer estimates the heat transfer in the usual type of cooler to be 50 to 100 per cent greater for hydrogen than for air. This, of course, is a big factor since the cost and size of the present cooler can be reduced.

The majority of the iron and copper losses in the core have to flow an appreciable distance through the iron to the ventilating surface. This necessarily requires a temperature drop. Where radial ventilation is used, the heat flow is mainly across the laminations, in which direction the heat flow has a high-resistance path due to the varnish and gas film between the laminations.

With one-watt flow across a 1-sq. in. section of the usual 0.017-in. varnished iron laminations, the temperature drops are approximately:

Deg. cent. drop through

Iron	Varnish	Gas		Total
1.0	11.0	(Air)	21.0	33 deg. cent.
1.0	11.0	(Hydrogen)	3.0	15 deg. cent.

Hence the rate of heat flow across the laminations should be at least doubled by using hydrogen as the cooling medium.

One of the most important portions of the heat-flow path is from the copper through the insulation. This part has more influence in limiting the rating than any other since the thermal conductivity of insulating materials is so low. The thermal resistance through ordinary insulation in air is about 3000 times greater than that through copper. All insulation in the built-up

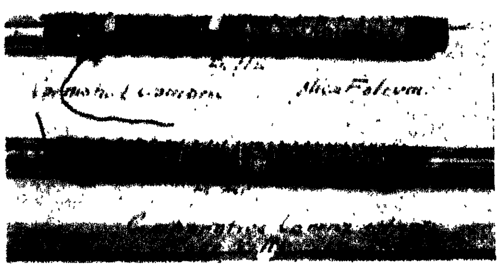
6. This was done on the basis of (K) being independent of the temperature of the gas and surface, which is practically true of the range in which we are interested.

wrapper will necessarily contain some small gas spaces; hence these gas spaces, if they are air, will offer considerable resistance to the heat flow, since the thermal resistance of air is about ten times that of the insulation itself.

To check the above, the Westinghouse Research Laboratory has made tests on the thermal conductivity of the insulation on turbo armature coils. The results show that the thermal conductivity of these mica insulations as used is from 150 per cent to 250 per cent as great with the coils in hydrogen as obtained on the same coils in air. The particular ratio depends upon the compactness of the insulation, that is, the percentage gas space in the wrapper. This increase in heat flow with the hydrogen cooling system will result in a considerable reduction of the conventional "hot spot."

The temperature of the rotor copper is usually the limiting temperature, with air as the cooling fluid. It will also tend to be the limiting factor when hydrogen is used, due to space limitations and to appreciable temperature drops through the solid iron core which will be unaffected by the gas used for cooling.

In the tests given by the writers, the apparatus simulated conditions found in a solid rotor where there would be a considerable temperature drop through the iron. However, in a ventilated rotor, even better results could be expected, since this drop through the iron would be reduced.



COMPARATIVE CORONA EFFECTS UNDER 15,000 VOLTS FOR 19 DAYS.

As to the insulation, the writer also agrees with the authors that its life would be materially increased in a hydrogen atmosphere. Oxygen in the air is the main factor which causes mechanical deterioration. Dr. C. F. Hill made tests regarding the corona action upon insulation in air and in hydrogen. The results were even better than those quoted in the paper in favor of hydrogen. Two kinds of insulation were tested, one varnished cambric, the other a mica wrapper. Both were wound on a glass tube and 15,000 volts a-c., 60 cycles, was applied for 19 days. Most of the stress was through the glass tube but a heavy corona could be seen covering the insulation. At the end of the test, the sample in hydrogen was unchanged, while the one in air was radically altered. The varnished cambric was bleached and was very brittle; the paper in the mica wrapper was completely destroyed. The hydrogen prevented the chemical action found on the sample in air.

As to the possibility of explosive mixtures with hydrogen, the average of nine investigations[7] gives the explosion limits as 7.9 to 69.4 per cent hydrogen in a hydrogen and air mixture.

An indicating or recording instrument for giving the purity of the mixture can be easily obtained by using the conductivity-cell bridge method[8]. This is exceedingly accurate and is well suited for such purposes.

Gases other than hydrogen can be used for a cooling medium. Thus helium (if made available in the future) is an inert gas with a density about $^1/_7$ of that of air. Its specific thermal capacity is about 73 per cent of that of air and its thermal conductivity is almost as high as that of hydrogen. Such a gas would be preferable to the operating men.

L. B. Bonnett: From the user's point of view, there are some very striking things in this Table II showing the results of the tests on the small 3000-kv-a. machine. If we can expect to get a one-third increase in capacity out of the same material, presumably at approximately the same price, we are getting something that is very interesting indeed. At that increased rating the total loss is practically the same, in fact, it has slightly decreased.

Looking at it from a little different point of view, many of us use stand-by machines that are in operation ready to take load, and the no-load losses are a very important factor. If the use of hydrogen can reduce those losses by, say, 50 per cent, that indeed is a very great advantage for this particular duty.

This light-load loss, too, has another rather interesting application. Turbo generators are commonly equipped with closed ventilation and air coolers and very frequently condensate is used for cooling. Since the light-load losses are usually more than half the full-load losses, the condensate at light loads has to be recirculated in a more or less complicated fashion or some other means of cooling supplied. This very great reduction in the fixed losses would mean that the losses would decrease more nearly in proportion to the load and the condensate itself might be perfectly adequate for cooling the machine all the way down.

With all the advantages mentioned in this paper—a really astonishing catalog of advantages—it behooves us, the users, not to be too sure that the one disadvantage, the possibility of an explosion, is an insurmountable defect. I believe our serious consideration is well worth while.

W. B. Kirke: It is hoped that further investigation on the life of insulating material when operated in hydrogen as compared to operation in air can be made. It might be found quite practical to operate at higher temperature limits in hydrogen than have been standardized for operation in air. It is also to be hoped that this paper will be supplemented by others which will indicate the installation cost of such a ventilating system and some idea of the equipment necessary for its operation.

C. J. Fechheimer: A few years ago the only media for cooling considered were air oil, and water. The use of oil or water has never met with favor in this country, even though certain important advantages could be secured by their adoption. It seems that electrical engineers were not aware until a few years ago that the gains to be obtained by means of some other gas were ufficient to warrant employing it instead of air. Even after the suggestion of the use of a lighter gas was offered to the designing engineers, they did not immediately consider its adoption. The gas proposed in the Schüler patent is hydrogen, and the first thought that entered the mind of the engineer was the danger of explosion. It was not until he learned that detonation will not occur if hydrogen constitutes more than about 70 per cent of a mixture with air that he felt that possible gains were great enough to warrant investigation. We now have records in this paper of the studies and researches given by three engineers of one of the leading electrical manufacturing companies on this subject. It is the first public presentation to a group of engineers of a systematic study of this advance which it is believed will considerably modify the design and construction of large electrical machines in the future.

Of the various gains to be obtained by means of hydrogen, there are two of prime importance. The first is the enormous reduction in windage loss due to the low density, and the other is the decrease in thermal drop through the insulation. In the large high-speed steam turbo alternator the windage is the greatest loss and may be as high as 50 per cent of the total. By substituting hydrogen for air this loss becomes almost negligible. In addition to the gain in efficiency, the temperature rise due to the windage becomes insignificant, whereas in the present day machine it is from 5 to 10 deg. cent.

It has been recognized for a number of years that the tiny

7. See article by C. J. Rodman, *Elec. World*, 6-24-22.

8. Thermal Conductivity for Analysis of Gases. Technical Paper, Bureau of Standards, No. 249.

voids in insulation reduce the net thermal conductivity of the wrapper to about 50 to 75 per cent of that which would obtain if the wrapper were solid throughout. Now we find that because hydrogen diffuses so readily hydrogen will supplant the air and the resistance to heat flow in the voids will be decreased to about one-seventh, and the net conductivity will be greatly improved. The authors find 30 to 58 per cent improvement in net conductivity for the field core, and they estimate about 42 per cent gain for the armature coil. Also, because the thermal conductivity is high, the transverse drop through a package of laminations is reduced. and the drop from the surface is decreased. So the authors find that as a result of all the gains, a certain turbo alternator can be rated about 30 per cent higher by substituting hydrogen for air. But that is not the final word; to take full advantage of the properties of hydrogen, the machine should be proportioned differently. For example, the velocities of the gas in the vent ducts can be increased, and the lamination-package thickness can be enlarged. Owing to the reduction in total losses, the volume per unit time of the gas may be lowered.

Also, as the authors state, there is a likelihood of reducing thickness of insulation wall in the stators when mechanical considerations do not enter. At present it is difficult to state how much the weight, cost and size of the generator may be decreased if full advantage of all gains is taken in the design. But certainly the cost will be reduced considerably.

There are a few points which are not covered in the paper. Two will be mentioned. In very large machines as designed at present, it is not feasible to evacuate in order to replace the air by hydrogen or vice versa, as the stresses arising from atmospheric pressure are prohibitive. While it is possible so to proportion those parts as to prevent collapse while evacuating, it is believed that an alternative plan which will maintain all parts at or near atmospheric pressure should be entirely satisfactory. The plan is to replace the air by an inert gas, such as nitrogen, and then to replace this inert gas by hydrogen. Tests are now being conducted for determining how satisfactorily this can be done.

Another feature is that to minimize leakage, suitable stuffing boxes should be provided where the shaft passes through the openings in the end bells. It seems at present that this is the most difficult part of the problem. Experimental work is now under way on a water-gland seal, and with this device it is believed that the leakage will be negligible. Ample precautions are being taken to avoid the escape of water into the generator.

The authors have used the thermal-conductivity method for determining the extent to which the hydrogen is contaminated. Another method consists of a small fan driven at constant speed, the inlet and outlet of which join into the system. The pressure which the fan generates is directly proportional to the density of the gas, and the pressure difference between the inlet and outlet can readily be indicated on an ordinary manometer. The relation between the percentage of hydrogen and the reading on the manometer is linear, assuming that air is the contaminating gas. The authors state that with the thermal conductivity method, 1 per cent impurity will change the potential drop from 11.5 to 12.5 volts or 8.7 per cent. With the density method, the same change in constituency will alter the manometer reading 13.3 per cent. Thus, there is greater sensitivity, and it is believed that the device is more direct and simpler than the thermal method. The density method can be used to operate a signal, or possibly to operate switches automatically.

While further experimental work must be done prior to the building of machines for service, the outlook is very bright, and it is believed that the time is not far distant when machines using hydrogen will be in operation.

J. Rosen (communicated after adjournment): The authors' investigations into the difficulties of ventilation of electrical machinery will be welcome as being of theoretical interest, more particularly as they have some bearing upon the conditions for generating at higher voltages than have been customary in the past. I do not think, however, that the use of hydrogen can be considered practicable at the present moment. It has the drawback of increased cost and complication in design. Further, I do not think that the danger of forming an explosive mixture can be altogether avoided. The closed-circuit system of ventilation has now been generally adopted for large alternators. The advantage with the use of hydrogen in avoiding the danger of fire also applies to the closed-circuit system using air, as, with the limited amount of air in the latter, the damage that can be done by fire is limited. I illustrate this by the following example:

The volume of air in the alternator and ducts of the closed-circuit system of a 25,000-kv-a. alternator at 3000 rev. per min. is approximately 2000 cu. ft. containing 40 lb. of oxygen. This quantity of oxygen could consume 15 lb. of carbon or 40 lb. of wood, but as the principal product of combustion is carbonic acid gas, and a flame is extinguished when only 4 per cent of carbonic-acid gas is present, the amount of wood consumed would only be about 2 lb. The total weight of combustible material in the alternator, including wood packing and insulation, exceeds 1000 lb. It is obvious therefore that the fraction of material that would be damaged or consumed by fire would be negligible.

To reduce the losses in the fans attached to the rotor body, I prefer to use separately driven fans, and to adopt a suitable system of ventilation to reduce the pressure drop through the alternator to a minimum. By this means, an improvement in efficiency of one per cent can be obtained. In the ventilation scheme described in the paper[9], "Some Problems in High-Speed Alternators and their Solution," the air-pressure drop through the alternator is reduced to approximately 3-in. water gage.

Robert Pohl: The valuable research which Messrs. Knowlton, Rice and Freiburghouse publish on this subject might with advantage be extended to the use of methane. In a paper published in 1923 (*Archiv. F. Elect.*, June 30, 1923, p. 361) I defined what one might term the cooling constant of various gases and showed that this constant is even higher for methane than for hydrogen. Since methane is also cheaply obtained as a by-product, its use may well be considered. Although the risk of explosion is not serious in any case the much smaller area of "exploibility" would be a practical advantage.

E. H. Freiburghouse: From the discussions it is evident that other engineers have also been giving active consideration to the subject and almost all of them seem very optimistic for the future use of hydrogen as a cooling medium for electrical machinery.

Opinions and data which have geen given seem, in the main, to agree quite well with those given in the paper. Although the points raised by Mr. Fechheimer were not covered in the paper, they have been carried out or considered during the investigation by the authors.

Mr. Fechheimer mentions the use of an inert gas, such as nitrogen, for replacing the air and hydrogen in the generator before and after the installation of the hydrogen. Nitrogen was used for this purpose during the heat tests which were made upon the 3380-kv-a. generator.

It was realized from the beginning that to prevent the leakage of hydrogen between the rotating and stationary parts of the generator was the most difficult and expensive problem to solve. Two different types of seals have been developed each of which reduces the leakage to a negligible value. In the liquid seal it is thought that oil is preferable to water.

A small fan driven at constant speed was used in some of our earlier investigations to determine the density of the gas mixture and, as Mr. Fechheimer states, it has several attractive features.

If hydrogen is used as a cooling medium, the authors believe that Mr. Rosen will agree that fans upon the rotor of the generator are preferable to separately driven fans. We believe that the pressure drop of the air through the generator should greatly exceed the 3 in. of water which Mr. Rosen mentions, if the necessary velocity of the air is obtained for a high value of unit-surface heat transfer.

Stored Mechanical Energy in Transmission Systems

BY J. P. JOLLYMAN[1]

Associate, A. I. E. E.

Synopsis.—The paper considers the performance of the stored mechanical energy in the moving masses connected synchronously to a transmission system during changes in load, changes in input, and changes of transmission capacity,

The stored mechanical energy greatly affects the performance of a transmission system during sudden changes in transmission line capacity occasioned by switching out or in a parallel circuit. Such switching operations lead to oscillations of input due to the interaction of stored mechanical energy and the altered difference in phase between generated and received voltages over a transmission line.

* * * * *

THIS paper will consider the performance of stored mechanical energy in a transmission system during changes in load, in input, and in transmission capacity.

Typical Transmission System

For this paper's purpose, a typical transmission system will be considered to consist of two or more generating plants connected to a network feeding load centers by double circuit lines of considerable length. Some generating capacity may exist near the load centers, but its existence or absence has little effect on the subject under consideration.

Mechanical energy is stored in every moving mass connected to a transmission system. The most important of these masses are those revolving elements the speed of which fluctuates with changes in system frequency. The rotors of synchronous machines, such as generators, synchronous motors, rotary converters and synchronous condensers, are of greater importance than the rotors of induction motors or the revolving parts of machinery driven by induction motors, because the synchronous machines must follow the system frequency precisely while induction motors have some slip. The stored energy in devices such as street cars connected to a transmission system in a non-regenerative manner does not influence the performance of the stored energy of the system.

Typical Flywheel Effects

The greatest flywheel effects per kv-a. of capacity will usually be found in the rotors of large generators. Typical flywheel effects are:

Large hydro unit – 27,000 kv-a., 225 rev. per min. $W R^2 = 5{,}000{,}000$.

Stored energy = 43,031,250 ft-lb. = 16.2 kw-hr. = 1590 ft-lb. per kv-a.

Small high speed hydro unit – 7500 kv-a., 514 rev. per min. $W R^2 = 200{,}000$.

Stored energy = 8,976,000 ft-lb. = 3.37 kw-hr. = 1195 ft-lb. per kv-a.

Synchronous condenser – 20,000 kv-a., 600 rev. per min. $W R^2 = 500{,}000$.

Stored energy = 30,600,000 ft-lb. = 11.5 kw-hr. = 1530 ft-lb. per kv-a.

Total Flywheel Effect of System

The total flywheel effect of a large transmission system is difficult to estimate but may be of the order of 2000 ft-lb. per kv-a. of connected generator capacity. Assuming 1.25 kv-a. of generating capacity for each 1.00 kw. of load, a five per cent increase in load will reduce the speed from 60 to 59 cycles in about two seconds, if the mechanical input is held constant.

Many classes of load decrease with a decrease of speed. Among these are centrifugal pumps and other motor-driven devices. Experience on a typical large transmission having a load of 300,000 kw. indicates a loss of about 3.5 per cent in load for a reduction in speed from 60 to 59 cycles and a corresponding gain for an increase of one cycle.

Performance of Stored Mechanical Energy During Load Changes

An addition of load to a transmission system does not cause an immediate increase in input of the governing generators. The governors are responsive to speed only; hence they cannot add input until the speed has dropped the 0.1 per cent to 0.2 per cent necessary to cause the governors to act. The additional load is supplied from the stored energy of the system while the speed is decreasing to a point where the governors start to act. The input is then increased until the speed returns to normal or until it returns to the speed corresponding to the load on the governing units, depending on whether the governor is adjusted to maintain a flat speed or a drooping speed.

Where two or more generating units are governing at the same time, their governors must be set with a drooping speed characteristic. In such cases the speed will not return to normal unless the synchronizing motors of the governors are readjusted.

A reduction in load causes a similar train of events.

1. Hydroelectric and Transmission Engineer, Pacific Gas & Electric Co., San Francisco, Cal.

Presented at the Pacific Coast Convention of the A. I. E. E, Seattle, Wash., Sept. 15-19, 1925.

The governing unit does not immediately decrease its input. The excess input increases the stored energy with the increase of speed necessary to bring the governor into action, whereupon the speed returns to normal.

A consideration of the events attendant upon a change of load shows the fallacy of a speed governor which is controlled by the electrical output of the governing unit. The only change in output occasioned by a change in load is the share of the total stored energy contributed by the governing unit. If the governing unit is to maintain speed it must be controlled by speed.

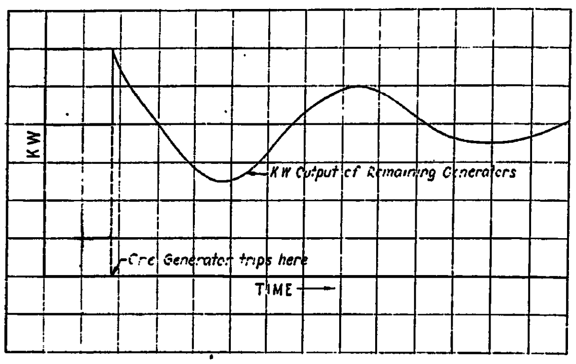

FIG. 1—OSCILLATION OF OUTPUT DUE TO SUDDEN LOSS OF GENERATOR

PERFORMANCE OF STORED MECHANICAL ENERGY DURING CHANGES IN INPUT

A generating unit may be separated from the system by the operation of a switch with the result of a sudden decrease of the input to the system.

The general effects are the same as when a load is suddenly applied. The stored energy of the system is drawn upon until the speed drops to a point where the governors begin to act.

A sudden decrease of input due to switching off a generator under load causes an oscillation of the stored energy of other generating units in the same or nearby plants with respect to the system at the receiving end of a transmission line. The flow of power over a transmission line is accompanied by a lag in time phase of the receiver voltage behind the impressed voltage. The difference in phase depends upon the length of the line and the amount of load carried. This difference in phase is analogous to the twist in an elastic shaft occasioned by a torque. The degree of twist between the ends of the shaft depends upon its length and the torque applied.

The sudden tripping of a generator under load leaves the remaining generators in the same plant in an angular position ahead of the angular position corresponding to the decreased input to the transmission line. These generators must drop back in angular position, hence, must slow down slightly and yield some of their stored mechanical energy. Finally, the generators must return to the system speed and the normal amount of stored energy. The process involves an oscillation of the angular position of the generators with respect to the synchronous equipment at the receiver end of the line with a corresponding oscillation of electrical output. This oscillation is independent of the mechanical output of the prime mover which will usually remain constant, since the changes in speed during the oscillation will usually be less than those required to cause the governors to act. Fig. 1 shows the character of this oscillation.

An increase in input as might be occasioned by a plant pulling up a block of load acts in a manner similar to a decrease of load—the stored energy is increased with the increase of speed to the point where the governors begin to act.

Since increases of input are usually less sudden than decreases due to the separation of a generating unit, the attendant oscillations are usually less pronounced. Such as occur are due to the increase in the phase angle over the line which must take place before the line can deliver additional load.

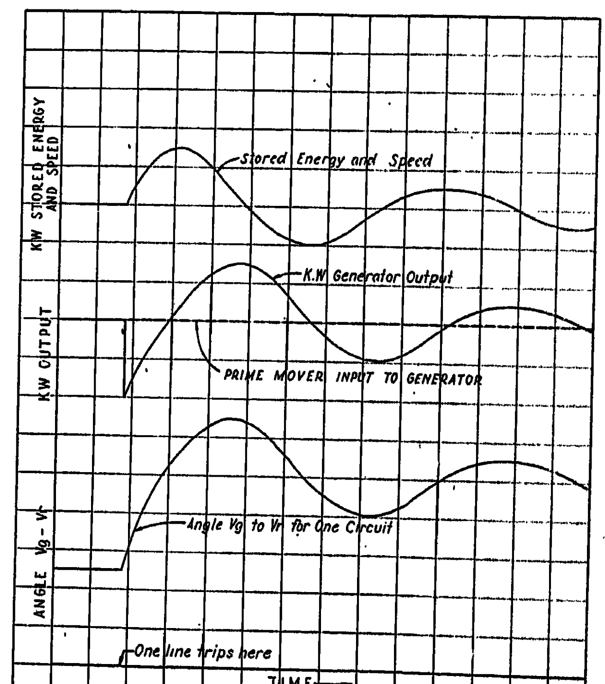

FIG. 2—OSCILLATIONS OF SPEED, STORED ENERGY, GENERATOR OUTPUT AND ANGLE BETWEEN GENERATOR AND RECEIVER VOLTAGE DUE TO ONE OF TWO PARALLEL TRANSMISSION LINES TRIPPING

THE PERFORMANCE OF STORED ENERGY DURING CHANGES IN TRANSMISSION LINE CAPACITY

Stored energy is an important factor in the performance of a transmission system during changes of transmission line capacity occasioned by switching out or in a parallel circuit. Such an operation results in a sudden change in the load on the line or lines remaining in service. The change of load on the line

requires a change in the angular position of the generator voltage with respect to the receiver voltage. This change in angular position requires a change in stored energy and the transition is accompanied by an oscillation.

The case most likely to cause difficulty is the loss of one of two parallel circuits when the load on the remaining circuit approaches the limit of synchronous stability. Under these conditions the oscillation in kilowatt input arising from the oscillation of the stored energy may result in an input which exceeds the stability limit even though the steady state input is considerably under the limiting load for the remaining line.

A better understanding of the subject may be had by considering the performance of the generators at the time one of two circuits is switched out. Reference is made to Fig. 2.

Preceding the instant the parallel line trips out, the angle between the generator and receiver voltage may be $n°$. When the circuit trips, the remaining circuit cannot carry the total load until its angle has become even more than 2 $n°$; hence the generator output drops to about half of its previous value and the excess of input from the prime mover increases the stored energy and the speed until the normal generator output is restored.

At this point the generator is running faster than the receiver; hence the output continues to increase until the excess stored energy is reduced to normal when the generator will be slowing down. Thus an oscillation of kilowatt output, angular difference between generator and receiver voltages and stored energy is started which may result in a maximum kilowatt input exceeding the limiting load the circuit can carry.

The performance of the transmission system under these conditions is greatly complicated by the fact that the sudden decrease in input attendant upon a line opening, starts an oscillation of the synchronous receiving apparatus with respect to the generators.

The period of oscillation of each synchronous unit will depend upon its $W R^2$ per kv-a. which will usually be different for each unit of different size or character. The resultant performance of the transmission system is extremely complicated and probably impossible to predict with accuracy. Observations indicate that the oscillations of energy flow in the transmission system are composed of several different frequencies superimposed.

Switching in a second parallel circuit also causes an oscillation of mechanical energy with the reverse effects to those observed for switching a line out. The generator output will be momentarily increased, followed by an oscillation. Such an operation is probably less likely to cause synchronous instability than switching out a parall elcircuit; however, a severe disturbance may be set up. A much better method of operation consists in transferring generators to the incoming line and equalizing the loads before the lines are paralleled at the generating plant.

Discussion

R. J. C. Wood: The outstanding point which struck me in this paper was the very small number of kilowatt-hours that are stored in the kinetic energy of the moving fly-wheel. Here is a 27,000-kv-a. unit and the total stored energy from full speed down to nothing is only 16 kw-hr. That seems to be such a small amount that it would not enter materially into any disturbances of the system, particularly as the whole of that 16 kw-hr. is not used since the speed will not drop from full speed to zero; the fluctuation will be very small and the amount of energy re eased will correspond to it.

L. N. Robinson: In connection with Mr. Jollyman's paper, it may be of interest to mention that it is intended to synchronize the 19,500-kv-a., hydraulic-turbine-driven generators at the Baker River Station automatically.

It is expected that this will facilitate operation and improve the service considerably. It will reduce the number of attendants to one on each shift. It is expected that automatic synchronizing will expedite the starting up and connecting of generators to meet changing load requirements and that it will be effective in restoring service quickly after serious interruptions.

Two speed switches are geared to the shaft of each of the generating units. One speed switch is closed when the speed of the unit is more than 95 per cent of normal speed and the other is closed when the speed is less than 105 pe: cent. The two speed switches are connected in series so that the circuit is closed only when the speed of the unit is within 5 per cent of normal. When he desires a unit to be synchronized automatically, the operator will turn a key switch on the main switchboard. This key switch connects the closing circuit of the generator oil circuit breaker through the speed switches and the oil circuit breaker will be closed automatically when the speed comes to within 5 per cent of normal. This procedure applies whether the machine is being started up or is coming back to normal after excessive speed due to sudden interruption of the load.

The generators are equipped with amortisseur windings, since they are intended to be thrown on the bus without d-c. field excitation, relying upon the induction-motor effect of the squirrel-cage winding to bring them nearly to synchronism. The automatic synchronizing control is interlocked with the generator field switches so that a generator cannot be thrown on the bus automatically unless its field switches are open.

As far as we know, these are the largest generating units to be equipped for automatic synchronizing up to this time, and they are of especial interest because each unit constitutes approximately 20 per cent of the present peak generating capacity of the system on which they are being installed.

J. P. Jollyman: While as Mr. Wood has pointed out, it is true that the fly-wheel effect of a large generator is only a few kilowatt-hours, still the total fly-wheel effect of a large system is sufficient to prevent the usual load changes from producing material speed changes within the time required for governor action.

Transmission Line Design

Mechanical Design of Spans With Supports at Unequal Elevations

BY G. S. SMITH[1]

Associate, A. I. E. E.

Synopsis.—The purpose of this paper is to derive a practical method of design based upon the catenary formulas for spans whose supports are not at the same elevation. It is furthermore intended completely to formulate the method for applying it to any cable which is suspended freely or is uniformly loaded, as well as for obtaining its characteristics after the temperature or loading conditions of the cable have changed.

After a brief survey of the present need for more accurate methods of mechanical design of transmission line cables, the several formulas which are adapted to spans with supports at unequal elevations are given, and the method of using them is fully explained. All such special formulas are fully derived in the appendix.

The first method given depends somewhat upon interpolated values from the symmetrical span data. A second pure interpolation method is next described which has the advantage of being shorter than the first as well as more accurate, since it depends upon fewer interpolated values from mathematical tables.

The use of these two methods is then fully illustrated by the solution of three typical spans. Data for the cable used in symmetrical spans are first given, and from these the solution for the span with supports at unequal elevation is obtained. For the purpose of comparison the computations used in obtaining the desired values by each method are given in full for one of the spans chosen.

These data are entered on a complete set of forms stating all formulas used and indicating by the headings of each column the operation performed to obtain the results recorded therein. These forms have been so arranged that by supplying the proper constants, they may be applied to any similar span problem, and thus will greatly reduce the work and the possibility of errors in the final results.

This affords a well defined method of making, to any desired degree of accuracy, computations which can be applied equally well to all types of spans with supports at any relative elevation.

* * * * *

IMPROVEMENTS in the methods of mechanical design of electrical transmission lines have scarcely kept pace with the advancement made in the electrical design. Most of the methods offered for the solution of the span whose supports are at the same elevation are based either upon the assumption that the cable takes the form of a parabola or upon some scheme of selecting the desired values from a set of curves. Few, if any, of these methods used in the past are capable of giving results with any great degree of accuracy. For the solution of the span problem, when the supports are not at equal elevations, the methods available are still fewer in number, and even more approximate in character.

Such methods were sufficiently accurate in the past, since the cost of the small lines used was not great in comparison with the total cost of the development. However, a very marked change has taken place in the last several years until now the cost of the transmission line is often a very important item. Both the increased capacity and more permanent type of construction demand larger spans than were previously used in order that the greatest economy may be obtained. Then again, we are now reaching out into the very rugged parts of the country for the water-power available there, and here also we find a stimulus toward the use of long spans to decrease the construction expense. Here also we find many, if not most, of the spans, with supports at unequal elevations. It is needless to say that economy and reliability in such construction demand the most accurate data obtainable.

In 1917 Professor Kirsten[2] presented before the Institute his paper on "Transmission Line Design," in which he offered a method of design for spans with supports at equal elevations, based upon the equation for the catenary curve. His method, as later improved[3], is capable of almost any degree of accuracy desired. This paper presents a somewhat similar method of design for those spans whose supports are at unequal elevations.

Since the formulas derived have a definite relation to those usually given for the catenary curve, this relationship will be next explained and the reasons why new formulas may be desired will be shown.

Catenary Equations with Higher Support as Origin of Coordinates

A flexible cable suspended from two points at an equal elevation forms a catenary symmetrical to these two points of support under all conditions of temperature or uniform loading. In this case the origin of coordinates may be taken at its lowest point where the tangent to the cable is horizontal. Thus only half of the span need be considered.

The value of X at the point the cable is fastened to the support will be equal to half the total span, and the corresponding value of Y will be the total sag of the cable for the load tempretaure and tension conditions existing. If we should raise or lower the supports so that the lowest point of the cable would always be at the same elevation, under varying load and temperature

conditions, the cable would take positions similar to those shown in Fig. 1.

In the catenaries shown, the tension at any point on the cable x distance from the origin may be expressed by the simple catenary equation given in hyperbolic functions; thus

$$T = c\,w \cosh \frac{x}{c} \tag{1}$$

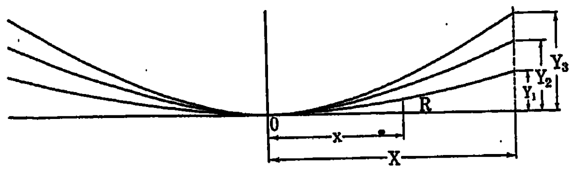

Fig. 1

Similarly the distance of the same point above the horizontal is expressed by

$$y = c \cosh \frac{x}{c} - c \tag{2}$$

and the equation for the actual length of the cable from O to R is

$$s = c \sinh \frac{x}{c} \tag{3}$$

The concept c is a constant for all points on any given catenary. It has a value equal to the length of cable whose weight is the same as the value of the horizontal tension, or the actual tension on the cable at the lowest point.

If the same cable is suspended from supports not at the same elevation, the point at which the tangent to the cable is horizontal does not lie midway between supports. Furthermore it changes its position for every change of temperature or loading. However, each of the various curves formed, is a portion of some symmetrical catenary similar to those in Fig. 1.

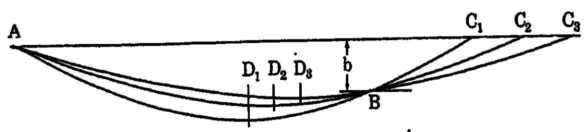

Fig. 2

Fig. 2 represents such a cable suspended between points A and B, showing three of its positions under three respective assumed temperature or loading conditions. Each curve is projected to the horizontal line $A\,C_3$. It is evident then, that each curve between A and B is a portion of a symmetrical catenary with the lowest points at D_1, D_2 and D_3 respectively. Obviously the simple catenary equations hold for any one curve referred to its lowest point as an origin, but this proves of little value since the origin shifts when the assumed conditions change. Thus the simple relations between the curves in Fig. 1 for various assumed conditions is lost for the similar curves in Fig. 2.

From the foregoing it is evidently desirable to derive the corresponding equations with the origin at one of the supports, which is a point on the resulting catenary under all conditions. Since the support A has the greater tension at all times, and will always be one of the ends of the resulting equivalent symmetrical catenary, it is the more desirable for the origin. Thus with the higher support as an origin, most of the values found in the tension-sag data for symmetrical supports can be substituted directly in the new formulas. The equations derived with A as the origin will hold equally well for B or D as the origin if proper substitutions are made.

Fig. 3 shows one of the curves in Fig. 2 with the various tensions, angles, etc., indicated. With the point A as the origin of coordinates, the following equations have been derived:

$$s = \frac{c}{\cos \beta_m} \left[\sinh \frac{x}{c} - \sin \beta_m \left(\cosh \frac{x}{c} - 1 \right) \right] \tag{13}$$

For the sag of the point p below the point A.

$$y = \frac{c}{\cos \beta_m} \left[\cosh \frac{x}{c} - \sin \beta_m \sinh \frac{x}{c} - 1 \right] \tag{14}$$

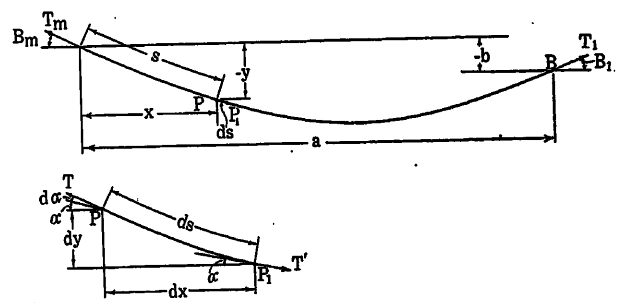

Fig. 3

and for the tension on the cable at point P

$$T = \frac{c\,w}{\cos \beta_m} \left[\cosh \frac{x}{c} - \sin \beta_m \sinh \frac{x}{c} \right] \tag{15}$$

The full derivation of these formulas is given in Appendix 1.

The following list will explain the symbols used in these formulas, as well as all others which will be used throughout the paper to specify special values.

w = weight per foot of cable in pounds
s = total length of the cable from A to any point P
x = any horizontal distance measured from A
X = half span length of the equivalent catenary with supports at the same elevation
y = sag at any point
Y = maximum sag corresponding to the value X on the equivalent catenary
T = tension at any point
T_m = tension at the upper support or at either support in the equivalent catenary
β = angle the tangent to the cable makes with the horizontal

β_m = value of β at the upper support

c = length of cable whose weight is equal to the horizontal tension on the cable

a = horizontal distance between supports of the span with supports not at the same elevation

b = difference in elevation of supports

d = maximum horizontal distance from the straight line between supports to the catenary

Equations (13), (14), and (15) are the generale quations for the catenary, assuming the origin of coordinates at the higher support. By substitution of the value of β at any point, P, for β_m, the formula will then be the equation for the catenary with the point P as the origin. Thus if the value of β is zero, which is true at the point where the tangent to the cable is horizontal, the formulas will reduce to the simpler expressions given in (1), (2), and (3).

The new equations derived might be used to solve spans with supports at any relative elevation, but the mathematics involved in finding the new span data after changing temperature or loading conditions would be very difficult. However, since the tension-sag data for spans of various lengths, with supports at the same elevation, are usually required for every line designed, certain parts of these data may be substituted in the foregoing equations to obtain the desired results for the span with supports on an incline.

Applications of Equations—First Method

In Fig. 4 two catenaries from the tension-sag data for symmetrical spans are shown as $A\,B_1$ and $A\,B_2$. These

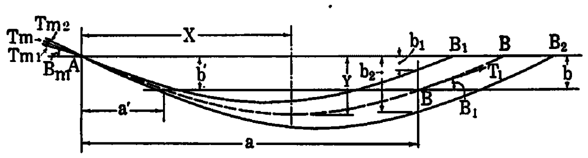

Fig. 4

are both at the same temperature and loading conditions but for different span lengths. The third catenary $A\,B'$ is the desired one, passing through its points of support A and B. Thus the part $A\,B$ is the actual cable suspended, and $A\,B'$ the equivalent symmetrical catenary.

All values of c, T_m, Y, X, and w are known for $A\,B_1$ and $A\,B_2$. Also the spacing (a) and the difference of elevation of supports (b) on $A\,B$ are known.

If in equation (12) the value (a) is substituted for x and also the values of c, $\cos\beta_{m1}$, and $\sin\beta_{m1}$ corresponding to the known curve $A\,B_1$, the resulting value of y will be the value indicated by b_1. If a similar substitution is made in (12), using values of c, $\cos\beta_{m2}$, and $\sin\beta_{m2}$ corresponding to curve $A\,B_2$, the resulting y will be the value indicated by b_2.

It is only necessary to compute the values of y for three or four of the known catenaries, and plot curves between these values of y, now given as b_1, b_2, etc., and the corresponding values of c, X and T_m. The desired values of c, X, and T_m will then be the points corresponding to b on these curves. The values of Y, w or any others may be found by a similar method, or may be computed.

The value X here is the half span length of the equivalent symmetrical catenary and Y the maximum sag of the same catenary.

It is obvious from Fig. 4 that there are two points on the curve $A\,B'$ which have the same difference of elevation from the support A. Thus b corresponds to span a, and b' corresponds to a'. In other words the desired catenary may have a total span a greater than the half span X of the equivalent symmetrical catenary, or a span a' which may be less. In the latter case the lowest point on the line is at the lowest support and the vertical component of strain upon this support will be upward.

An inspection of the data given later will show that no large amount of computing is necessary for obtaining the tension sag or any other data for a given span with supports at unequal elevations. Many of the desired values have already been given in the data for supports at equal elevations. Thus in equation (14) a is substituted for x and the result is the required value b.

$$b = \frac{c}{\cos\beta_m}\left[\cosh\frac{a}{c} - \sin\beta_m \sinh\frac{a}{c} - 1\right]$$

It is shown in Appendix 1 that

$$\frac{c}{\cos\beta_m} = \frac{T_m}{w}$$

But the tension equation for the symmetrical span is

$$\frac{T_m}{w} = c\cosh\frac{x}{c} = \frac{c}{\cos\beta_m} \qquad (17)$$

where x is now the half span. The value of $c\cosh\dfrac{x}{c}$ is given for each assumed condition in the data under Col. (21) in each table. Also from (41)—

$$\cos\beta_m = \frac{1}{\cosh\dfrac{x}{c}}$$

and

$$\sin\beta_m = \left[1 - \cos^2\beta_m\right]^{1/2} = \left[1 - \frac{1}{\cosh^2\dfrac{x}{c}}\right]^{1/2} \qquad (18)$$

The values of $\sinh\dfrac{a}{c}$ and $\cosh\dfrac{a}{c}$ may be interpolated from the tables of sinhs and coshs.

In carrying through the calculations for the method just described, it was found that the same results might be obtained with less than half the computations involved here, by a pure interpolation method. The designer will doubtless choose the second method,

APPLICATIONS OF EQUATIONS—SECOND METHOD

This alternate method of solving the span with supports on an incline depends only upon formulas given in equations (1), (2), and (3) together with the usual tension-sag data for spans with supports at the same elevation.

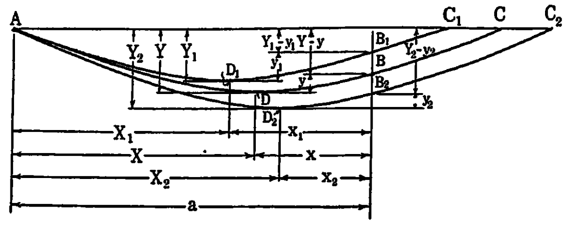

FIG. 5

In Fig. 5, let the catenary whose values are desired be represented by $A\,D\,B$ with supports at A and B. The difference in elevation of supports will be b and the total span length a. If the origin of coordinates is at point D, this will be a portion of an equivalent catenary $A\,D\,C$, symmetrical about an axis at D and with half span values of X and Y. Every point on this curve can be expressed by the equation,

$$y = c\left(\cosh\frac{x}{c} - 1\right)$$

The value c is constant for the whole length of the curve. If the value of X were known, the value of x could be found, since

$$x = a - X$$

The difference between the elevations of D and B could be found by

$$y = c\left(\cosh\frac{x}{c} - 1\right)$$

and

$$b = Y - y$$

However, the value of X is still unknown.

Now imagine an infinite series of catenaries, some shorter and some longer than the desired one, $A\,D\,C$. These were all suspended with the same maximum tension, under maximum loading and minimum temperature conditions, and they have all been subjected to the same loading and temperature changes.

If $A\,D_1\,C_1$ is one of the catenaries in this series with a total span length $A\,C_1$ an infinitesimal amount shorter than $A\,D\,C$, it will have half span values of X_1 and Y_1. The value y_1 may also be found for x_1 where

$$x_1 = a - X_1$$

Thus

$$y_1 = c\left(\cosh \frac{x_1}{c_1} - 1\right)$$

It is very evident from the sketch that $Y_1 - y_1$ will be less than $Y - y$, since Y_1 is less than Y, and y_1 is greater than y.

In a similar manner, a span an infinitesimal amount larger may be represented by $A\,D_2\,C_2$, and with similar reasoning $Y_2 - y_2$ can be proven greater than $Y - y$.

If $Y_1 - y_1$ is an infinitesimal amount smaller than b, and $Y_2 - Y_2$ is an infinitesimal amount larger than b, the point b must be one of a series of such sag differences, each corresponding to one of the series of catenaries having A as one support and the other support at a horizontal distance of a out on the curve. In other words, the catenary of this series, upon which b is one point, can be interpolated from the infinite series.

By choosing values of $\frac{x}{c}$ with differences as small as is desired, an infinite series of catenaries, related as was previously described[4], can be approached. However, if the point b and its corresponding catenary can be

4. That is, with the same maximum tension on all catenaries of the series at the maximum loading and minimum temperature conditions, and the same temperature and loading conditions for all of this series, which is the original series after changing from the critical to the desired condition.

interpolated from an infinite series, it can also be interpolated from a finite series.

The desired results are easily obtained from the usual tension-sag data by carrying out on several of the catenaries the operation described, obtaining values similar to $Y_2 - y_2$ greater than b, and others similar to $Y_1 - y_1$ less than b. These sag differences may then be plotted against their corresponding values of X, c, or T_m, and the value of X, c_1, or T_m, corresponding to the catenary upon which b is one point, may readily be found. Other values, such as Y and w, may be found in a similar manner, or may be computed.

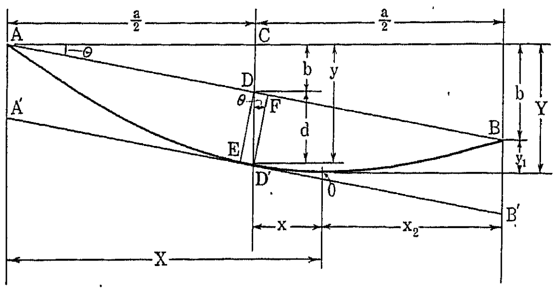

FIG. 6

METHOD OF OBTAINING MAXIMUM SAG OF CATENARY FROM STRAIGHT LINE BETWEEN POINTS OF SUPPORT

The two methods just explained will give all of the information necessary if the line is to be strung by means of a tension dynamometer, or if the sag Y can be used. However, in stringing cables over supports on an incline, it is often more convenient to measure off the

vertical distances $A A'$ and $B B'$ shown in Fig. 6 and while sighting between points $A' B'$ to allow the cable to sag until it is tangent to the line of sight.

The usual method of finding the value of $A A'$, which corresponds to $D D'$, is to assume that the maximum

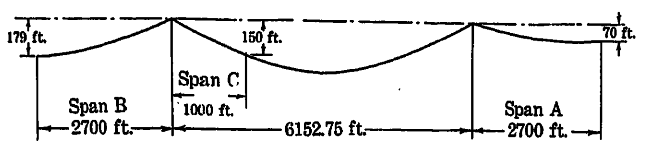

FIG. 7

deflection of the cable appears at a point E, which is also one point on the line perpendicular at $A B$ at its middle point. This assumption would be correct if the curve were a parabola, but it is not true for the catenary.

It is proved in Appendix No. 2 that the point of maximum deflection of the catenary from the line between the points of support occurs at the center of the span in certain cases, and so near the center in all other cases that a considerable degree of accuracy must be attained to detect the difference. Thus the value $D' F$ may be considered the true maximum deflection. The vertical distance, $D D'$, will be equal to $D' F \cos \theta$.

However, the value of $D D'$ may be computed directly from the data obtained by either method. Using equation (**14**), the value for y, which is shown as $C D'$, will be obtained by substituting $\frac{a}{2}$ for x. Also from the right triangle $A C D$, $C D = b' = \frac{b}{2}$ since it is at the center of the span. Then $D D' = d = y - b'$. This

value of maximum deflection is given in the column with the heading d in the table.

The computations to obtain d may be simplified still further by the use of equation (2) instead of (14). The origin will then be at the lowest, or center point, of the equivalent catenary. This method will be evident from the calculations used in Appendix No. 2.

Demonstration of the Use of Methods Explained

The use of the methods described is illustrated by the solution of the following problem which arose in some preliminary work on the Tacoma Lake Cushman Power Project.

The transmission line crossing "The Narrows" for the Tacoma Cushman Power Project was originally planned with a main span of 6152.75 feet between two supports at the same elevation. On either side of this main span, a counter span was planned, using the same cable. This is shown in Fig. 7. The span A was assumed to have supports with a horizontal spacing of 2700 feet and with a difference in elevation of 70 feet. Span B has supports with the same horizontal spacing, but with a difference of elevation of 179 feet. To illustrate the solution on a short steep slope, a third span C was assumed with its supports 1000 feet apart horizontally, and with a difference of elevation of 150 feet.

This study was made on a one-inch plow steel cable with a maximum breaking strength of 240,000 pounds per square inch. The elastic limit of the cable was taken at one-half of the breaking strength and this

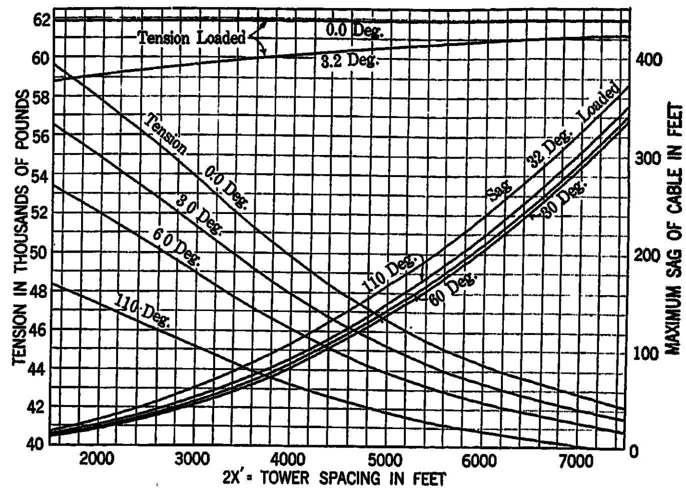

Fig. 8—Temperature-Tension Stringing Chart for One-Inch Diameter High Strength Steel Cable

again reduced 10 per cent for galvanizing, giving 108,000 pounds per square inch as the maximum allowable tension on the cable. All other specifications and constants are given in Table I.

as it was later revised. Fig. 8 shows a complete set of tension-sag curves for various lengths of spans.

Tables VI and VII show the computations for span B obtained by using the first method described, while Table VIII shows the application of the second method to the same span. An inspection of the results obtained by the two methods shows no appreciable difference. The second method illustrated by Table VIII should be the more accurate since it depends upon fewer values interpolated from hyperbolic tables.

Table IX gives the data for all three spans in tabulated form, while Fig. 9 shows the temperature-tension and temperature-sag curves plotted from the data given. It might be noted that considerable more data were computed than would usually be required in a design problem.

Charts with curves showing data for a wide range of conditions may be made with a small amount of additional computations. Thus, Fig. 10 shows a set of tension curves for spans 2700 feet in length but with various differences in elevation of supports. Curves covering a range of differences in elevation of supports several times that shown in Fig. 9 may be interpolated from the data shown in Table VIII without further computations.

Other useful charts might show tension or deflection values for a range of span lengths, with each curve representing a single difference in elevation of supports as well as a definite temperature condition. Such a chart would require computations similar to Table VIII for four or five different span lengths. With this amount of data, a series of charts could be made which would cover all of the varying conditions of practically any line.

Since the method of design presented here requires the computations for the usual tension-sag data, it is somewhat longer than most methods given. However, in the usual design of a transmission line the tension-sag data for the various symmetrical spans are always required. Thus the computations for the spans with supports on an incline require little additional labor, while in the design of very long spans the additional labor required is more than compensated for by the complete, definite, and accurate results obtainable.

Appendix No. 1

The conditions for the derivation of the formulas, with their origin at the upper support, may be obtained from Fig. 3.

Let S = total length of the cable between A and B: Then the total weight of the cable suspended is

$$w\,S = T_m \sin\beta_m + T_1 \sin\beta_1 \qquad (4)$$

The horizontal tension must be the same at each end

$$T_m \cos\beta_m = T_1 \cos\beta_1 = c\,w \qquad (5)$$

where c is the length of cable whose weight is equal to the horizontal tension. From the above

$$\cos\beta_m = \frac{c\,w}{T_m} = (1 - \sin^2\beta_m)^{\frac{1}{2}} \qquad (6)$$

Other useful relations may be derived from the enlarged sketch. Thus, horizontal tensions are equal throughout the span;

$$T_m \cos\beta_m = T\cos(\alpha + d\,\alpha) \qquad (7)$$

Vertical tensions may be expressed thus:

$$T_m \sin\beta_m - T\sin(\alpha + d\,\alpha) = w\,s \qquad (8)$$

With $d\,s$ at its smallest limit

$$\cos(\alpha + d\,\alpha) = \frac{d\,x}{d\,s} \text{ and } \sin(\alpha + d\,\alpha) = -\frac{d\,y}{d\,s} \qquad (9)$$

From the triangle relation of forces

$$T^2 = [\,T\sin(\alpha + d\,\alpha)\,]^2 + [\,T\cos(\alpha + d\,\alpha)\,] \qquad (10)$$

Extracting sq. root and substituting (7), (8), and (9) in (10):

$$\frac{d\,x}{d\,s} = \frac{T_m \cos\beta_m}{[\,T_m^2 - 2\,w\,s\,T_m \cos\beta_m + w^2 s^2\,]^{\frac{1}{2}}} \qquad (11)$$

From (5)

$$\cos\beta_m = \frac{c\,w}{T_m} = [\,1 - \sin^2\beta_m\,]^{\frac{1}{2}} \qquad (12)$$

$$c^2 w^2 = T_m^2 - T_m^2 \sin^2\beta^2 \qquad (13)$$

Substituting (12) and (13) in (11),

$$d\,x = \frac{c\,w\,d\,s}{[T_m^2 - 2\,w\,s\,(T_m^2 - c^2 w^2)^{\frac{1}{2}} + w^2 s^2\,]^{\frac{1}{2}}}$$

Let $T_m = K\,w$

$$d\,x = \frac{c\,d\,s}{[\,K^2 - 2\,s\,(K^2 - c^2)^{\frac{1}{2}} + s^2\,]^{\frac{1}{2}}}$$

$$x = \int_0^s \frac{c\,d\,s}{[K^2 - 2\,s\,(K^2 - c^2)^{\frac{1}{2}} + s^2\,]^{\frac{1}{2}}}$$

$$\frac{x}{c} = \log \frac{s - (K^2 - c^2)^{\frac{1}{2}} + (K^2 - 2\,s\,[K^2 - c^2]^{\frac{1}{2}} + s^2)^{\frac{1}{2}}}{K - (K^2 - c^2)^{\frac{1}{2}}}$$

But $K = \dfrac{T_m}{w} = \dfrac{C}{\cos\beta_m}$ and $\dfrac{1}{\cos^2\beta_m} - 1 = \tan^2\beta_m$

Substituting and taking log

$$\epsilon^{\frac{c}{x}} = \frac{s\cos\beta_m - c\sin\beta_m + (c^2 - 2\,s\,c\sin\beta_m\cos\beta_m - s^2\cos^2\beta_m)^{\frac{1}{2}}}{c - c\sin\beta_m}$$

Squaring and collecting terms

$$s = c\left[\tan\beta_m - \tan\beta_m\left(\frac{\epsilon^{\frac{c}{x}} + \epsilon^{-\frac{c}{x}}}{2}\right) + \sec\beta_m\left(\frac{\epsilon^{\frac{c}{x}} - \epsilon^{-\frac{c}{x}}}{2}\right)\right]$$

$$s = \frac{c}{\cos\beta_m}\left[\sin\beta_m - \sin\beta_m\cosh\frac{x}{c} + \sinh\frac{x}{c}\right]$$

$$s = \frac{c}{\cos\beta_m}\left[\sinh\frac{x}{c} - \sin\beta_m\left(\cosh\frac{x}{c} - 1\right)\right] \qquad (14)$$

This is the general equation for the actual length of

cable between one support and any point on the catenary x distance from support. β_m is the angle between the tangent to the wire at the point of support and the horizontal, the value of which may be found by the relationship given in (12).

In a manner similar to that above, the equations for the sag $-y$ or tension T for any point on the catenary at x distance out may be derived as follows:

$$\frac{T_m \sin\beta_m - w\,s}{-\dfrac{d\,y}{d\,s}} = [(T_m \sin\beta_m - w\,s)^2 + (T_m \cos\beta_m^{2}]^{1/2}$$

$$-\frac{d\,y}{d\,s} = \frac{T_m \sin\beta_m - w\,s}{[T_m^2 - 2\,w\,s\,T_m \sin\beta_m + w^2\,s^2]^{1/2}}$$

And from (5)

$$-\frac{d\,y}{d\,s} = \frac{c\,w \tan\beta_m - s\,w}{\left[\dfrac{c^2\,w^2}{\cos^2\beta_m} - 2\,c\,w^2\,s \tan\beta_m + w^2\,s^2\right]^{1/2}}$$

$$d\,y = \frac{s - c\tan\beta_m}{\left[\dfrac{c^2}{\cos^2\beta_m} - 2\,c\,s \tan\beta_m + s^2\right]^{1/2}}\,d\,s$$

$$y = \int_0^s \frac{s\,d\,s}{\left[\dfrac{c^2}{\cos^2\beta_m} - 2\,c\,s \tan\beta_m + s^2\right]^{1/2}}$$

$$- c\tan\beta_m \int_0^s \frac{d\,s}{\left[\dfrac{c^2}{\cos^2\beta_m} - 2\,c\,s \tan\beta_m + s^2\right]^{1/2}}$$

$$y = \left[\frac{c^2}{\cos^2\beta_m} - 2\,s\,c \tan\beta_m + s^2\right]^{1/2} - \frac{c}{\cos\beta_m}$$

But the value of s is given by equation (14). Substituting and simplifying,

$$y = \frac{c}{\cos\beta_m}\left[\cosh\frac{x}{c} - \sin\beta_m \sinh\frac{x}{c} - 1\right] \qquad (15)$$

Again substituting (7) and (8) in (10),

$$T^2 = [\,T_m \sin\beta_m - w\,s\,]^2 + [\,T_m \cos\beta_m\,]^2$$
$$T^2 = T_m^2 - 2\,T_m \sin\beta_m\,w\,s + w^2\,s^2$$

Substituting values from (12) and (14),

$$T = \frac{c\,w}{\cos\beta_m}\left[\cosh\frac{x}{c} - \sin\beta_m \sinh\frac{x}{c}\right] \qquad (16)$$

Appendix No. 2

An investigation to find the position on the catenary of the point which has a maximum deflection from the straight line between the points of support of the catenary shows some interesting results.

Referring to Fig. 6, the catenary $A D' B$ will have a maximum deflection from line $A\,B$ at some point near the middle of the span. At the point of maximum deflection, the tangent line will have the same slope as $A\,B$, which is $-\dfrac{b}{a}$. The method to be used in finding the position of the point of maximum deflection will be to assume that the tangent at the middle point, D, has the same slope as line $A\,B$, and to compute the error found in making this assumption.

With the origin of the catenary at 0, the value of vertical deflection from point 0 is given by equation (2)

$$y = c\cosh\frac{x}{c} - c$$

The slope of the tangent at any point on the cable is the first derivative of the foregoing equation, or

$$\frac{d\,y}{d\,x} = \sinh\frac{x}{c} \qquad (19)$$

If x is the value at which the cable has a maximum deflection from line $A\,B$, then

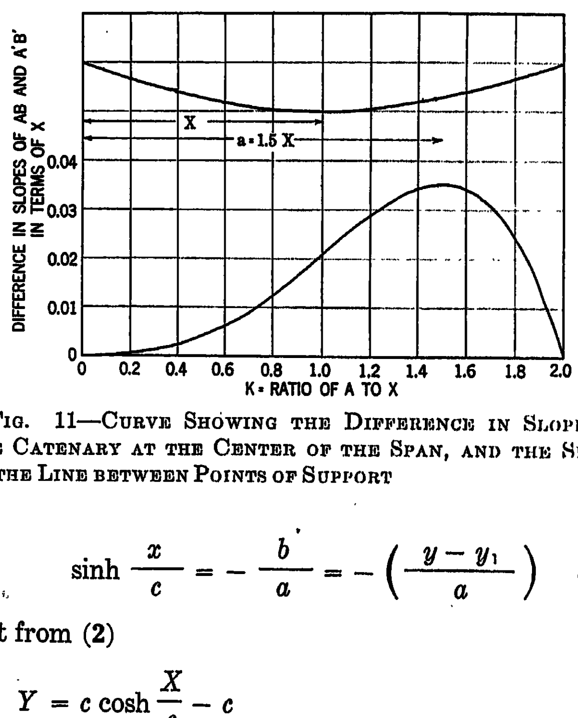

FIG. 11—CURVE SHOWING THE DIFFERENCE IN SLOPE OF THE CATENARY AT THE CENTER OF THE SPAN, AND THE SLOPE OF THE LINE BETWEEN POINTS OF SUPPORT

$$\sinh\frac{x}{c} = -\frac{b}{a} = -\left(\frac{y - y_1}{a}\right) \qquad (20)$$

But from (2)

$$Y = c\cosh\frac{X}{c} - c$$

and

$$y_1 = c\cosh\frac{x_2}{c} - c = c\cosh\frac{a - X}{c} - c$$

Substituting these values in (20)

$$\sinh\frac{x}{c} = -\frac{c}{a}\cosh\frac{X}{c} + \frac{c}{a}\cosh\frac{a - X}{c} \qquad (21)$$

The hyperbolic function may be expressed as a series. Thus if the first two terms for the sinh and the first three for the cosh are substituted, in (21), the error will be very small, since the next term in the series is of the

fifth power, and the ratio of $\frac{x}{c}$ is never greater than ⅓.

Then $\frac{x^5}{c^5\,/5}$ will be of the order .000034 +.

Evaluating equation (**21**) thus,

$$\frac{x}{c} + \frac{x^3}{6\,c^3} = -\frac{X^2}{2\,a\,c} - \frac{X^4}{24\,a\,c^3} + \frac{(a-X)^2}{2\,a\,c} + \frac{(a-X)^4}{24\,a\,c^3}$$

or

$$x^3 + 6\,x\,c^2 = 3\,a\,c^2 - 6\,X\,c^2 + \frac{a^3}{4} - a^2\,X + \frac{3\,a\,X^2}{2} - X^3 \quad (22)$$

If x_1 is substituted for x in (**22**), the portion before the equality sign will be the slope of the tangent at the middle of span a.

Thus from Fig. 6,

$$x = -\,x_1 = -\left(X - \frac{a}{2}\right)$$

Substituting and simplifying, but keeping all terms belonging to each value of slope on its side of the inequality sign, we have only the terms which do not cancel out.

TABLE X

K Ratio of a to X $a = K\,X$	Difference in slopes of lines $A\,B$ and $A'\,B'$
	In terms of X
2.	0.0
1.9	0.0143
1.8	0.0243
1.7	0.0307
1.6	0.0341
1.5	0.0352
1.4	0.0342
1.3	0.0320
1.2	0.0288
1.1	0.0248
1.0	0.0208
.8	0.0128
.6	0.0063
.4	0.0021
.2	0.0003
0	0

$$\frac{a^3}{8} - \frac{3\,a^2\,X}{4} = \frac{a^3}{4} - a^2\,X \quad (23)$$

A careful analysis of all the terms to the right and left of the inequality sign in the operation indicated above would disclose the fact that all terms would cancel if only the first term of the sinh series and the first two terms of the cosh series were used. In other words, using these first two terms as an approximation of the true value, the point of maximum deflection would always be at the center of the span. The terms in the inequality (**23**) constitute only a small portion of the total number of terms in the total slope value.

The numerical value of (**23**) would be the difference in the slope values for the two straight lines $A\,B$ and $A'\,B'$. Since the term on the left is the smaller, the desired point on the catenary must be a little nearer the higher support.

Evaluating (**23**) with a given in terms of X, the difference in slopes, also given in terms of X, may be found for any assumed value of a. The results are shown in Table X and the corresponding curve in Fig. 11. Thus (**23**) is an equality if a is equal to $2\,X$ or to zero. The point at which the difference is greatest occurs when $a = 1.5\,X$ appx.

TABLE XI

a 1.5 X

			To satisfy equation 24	% error in terms of
.333	1	3	−0.2525	0.17
.250	1	4	−0.2515	0.10
.200	1	5	−0.2509	0.06

To determine just how far from the center of the span the desired point on the catenary lies, values of c and a, both expressed in terms of X, may be substituted in (**22**). Then a value of x which will satisfy the equation may be found by inspection. Thus to find the greatest possible variation, let $a = 1.5\,X$. Then

$$x^3 + 6\,c^2\,x = -\,1.5\,X\,c^2 - 0.1563\,X^3 \quad (24)$$

The ratio of $\frac{x}{c}$ is a variable for different spans and increases in value as the tension is decreased or as the weight of the cable is increased, other conditions remaining constant. However, the value of the ratio $\frac{x}{c}$ will probably never be found as high as ⅓, and in all practical design problems will range between ¼ and 1/5.

Assuming $X = 1$, and $c = 4$, equation (**24**) will be satisfied by $x = 0.2515$ approx. From Fig. 6, if $X = 1$, and $a = 1.5$, $\frac{a}{2}$ will have the value of 0.75, and x_1 will be − 0.25. The difference between x and x_1 is a true measure of the error with the values assumed; that is,

TABLE XII

Span	Temp. deg. fahr.	K $a = K\,X$	Ratio $\frac{X}{c}$	At center	At point 5 ft. toward higher support	At point 5 ft. toward lower support
A	32	1.47	0.097	48.226	48.225	48.225

C	32	0.30	0.175	6.672	6.658	6.658
C	0.0	0.28	0.173	5.854	5.854	5.853
C	30	0.27	0.173	5.966	5.966	5.966

when $\frac{x}{c} = \frac{1}{4}$, the true point of maximum deflection lies 0.0015 X from the center point of the span. This is an error of 0.1 per cent when considered in terms of a.

Since the values of deflection are nearly equal for a considerable distance on either side of this maximum point, the per cent of error caused by assuming the maximum deflection at the center point is still smaller.

Table XI gives the distances of the true maximum points from the center of the span, as well as the per cent of error for $a = 1.5$, and for three assumed ratios of $\frac{x}{c}$.

Table XII gives the deflection of the catenary from the straight line between supports, as computed from the data given in Table IX. In each case three points on the catenary were selected, one at the center of the span, and one five feet on either side of the center. In almost every case these data clearly indicate the same facts proved by the foregoing discussion.

Discussion

F. K. Kirsten: I wish to congratulate Mr. Smith on his courage in using the catenary equations for the analysis of spans supported from points at unequal elevations, and I would also like to make some supplementary comments.

We know that the more closely we wish to describe a physical phenomenon by means of mathematical formulas, the more involved and unwieldy these formulas become. As an illustration, we might use the simple equation of a circle to express the location in space of a suspended cable, and describe actual conditions with sufficient accuracy although the assumptions involve considerable error. By a closer analysis of the forces in action we find, however, that the parabola describes actual conditions better than the circle and hence the application of the parabola yields greater accuracy, although the mathematical operations are more involved. But still a considerable error is made in the assumption that the weight per unit projected length of the span is uniform along the span. The demand for greater accuracy forces us to base our mathematical formulas upon the assumption that the weight per unit length of span, measured along the span, is constant. This assumption leads us to the catenary, a rather involved mathematical stratagem. This mathematical form is rather difficult to handle, especially if temperature changes accompanied by stress changes must be covered by its use. And still the catenary equation does not describe conditions with absolute accuracy. Since the tension changes along the span, the weight per unit length of cable cannot be uniform. But an attempt to involve this actual condition in the modification of the catenary form would lead to unmanageable expressions.

It will be apparent from a perusal of Mr. Smith's work that the chief difficulty in applying the catenary equation to spans of unequal elevations resides in the introduction of the slope of the suspension points into equations which are already complex enough for ready manipulation. Especially do we feel a naturally increasing reluctance to use the catenary analysis if changes of wind and ice loading together with temperature variations over a considerable range must be accounted for by proper mathematical operations with the catenary form. It is, therefore, in my opinion, a step in the right direction to adhere to the simple catenary forms which Mr. Smith ingeniously introduces into his second method instead of using the first method supported by equations **12**, **14**, and **15**.

We now have, thanks to Mr. Smith's work, a simple catenary analysis of spans of unequal elevation, and there cannot be any excuse for the use of parabolic forms in the future. It must be remembered that the catenary method is independent of fixed mass and space units; hence all span conditions which may occur in practise may be expressed by a series of curves from which by interpolation any span, at any slope, for any size or material of cable or any temperature range, may be read at once. This set of curves is as readily applied, without modifications by constants, in continental Europe where the metric system is used, as in the lands of inches, pounds and quarts.

Another important finding in Mr. Smith's paper, I believe, is the discovery that the point of maximum deviation from a straight line connecting any two points of unequal elevation of the cable in suspension occurs midway between the points of support in the middle of the span. This naturally facilitates a check upon the strain of a cable from points of unequal elevation by dropping targets from point B_2 to point A, of predetermined length, the line of vision touching the point of maximum deflection from the line joining these two points.

R. J. C. Wood: Our engineering department has done a good deal of work in calculating sags and we went into this question of catenary versus parabola quite fully and find that up to about a 1000-ft. span, the parabola is practically a satisfactory curve to use. It must be remembered that after the mathematician has figured out the sag of the line, some fellow in overalls is going to pull that line up as near as he can to either the predetermined sag or tension.

We have been a little undecided as to whether to use the sag or the tension in the line as the criterion. At one time we have used one and at another time the other. We have finally decided to use a dynamometer to measure the tension in the new line. The maximum tension under worst conditions will be about 12,000 lb. and under ordinary stringing conditions may be 6000 or 7000 lb. The dynamometer will probably read within 200 lb. so that any extreme refinement of calculation as to the desired tension is not necessary.

I do not wish to detract in any way from the fine work of mathematicians who calculate these things because, while we may be able to use the laws of a parabola up to a certain point, yet we depend upon the mathematician to tell us where that point is and from where on we should use the more accurate formula. We have ourselves used the catenary formula in all long-span work.

Our spans run up to about 3000 ft. and for that length of span the catenary is necessary. We have had to go a little further than indicated in Mr. Smith's paper, because we have found it quite necessary to calculate clearances to ground under wind conditions. In building the line on a hillside it is not only necessary to know the vertical clearance in still air, but it is quite essential to know that the line will not blow onto the ground when the wind is crosswise, so we have to calculate those conditions of load applied sideways.

It leads to some very interesting mathematics when there are, for instance, two spans which are dead-ended at the outer ends and hanging on a string of suspension insulators at the middle support, and the wind blows sideways, because the two spans then no longer remain in a plane but become a warped figure and the catenary calculations become quite involved.

C. E. Magnusson: Reference to the parabola by Mr. Wood leads me to bring out a point on the use of hyperbolic functions. Many engineers seem to think that using hyperbolic functions in connection with engineering problems is throwing out a smoke screen to prevent the reader from following the argument. They do not appreciate that for certain types of problems hyperbolic functions become a very convenient means for obtaining accurate solutions. A few years ago while discussing a problem with a

nationally prominent engineer, one who has presented many papers before the Institute, I suggested that for an accurate solution hyperbolic functions should be used, and was astounded to find that he had no idea as to what type of problems would require hyperbolic functions. As there may be others in the same predicament let me state that the basis for using circular or hyperbolic functions is simply this: A rotating vector of constant magnitude can be fully represented by circular functions, but if the radius vector varies in length while changing in phase position hyperbolic functions fit the case. For example, the voltage and current functions along a transmission line vary in magnitude as well as in time-phase position and hence require hyperbolic functions as they cannot be correctly expressed by circular functions.

R. W. Sorensen: I want to second the motion on hyperbolic functions. Dr. Kennelly of Harvard has been trying for years to get us to use them. I have been trying for about fifteen years to get engineering classes to use them, and they use them just as readily as they use trigonometric functions if you once start them off.

L. J. Corbett: The paper given by Mr. Kirsten[1] a number of years ago is, I think, a classic in its field of the application of hyperbolic functions to catenaries and long spans. I think Mr. Smith's paper is a very creditable companion paper to that one.

I like particularly Fig. 4 in which the common point A is used as a basis instead of the usual method, although I have not had time to check it and see whether there are particular advantages to be gained over the old method of calculating sag from the inclined line between A and B.

Mr. Smith, in his discussion, brought up also a point in which we were very much interested in the re-insulation of the Carquinez crossing of the Pacific Gas & Electric Company, and that is the difference in expansion between a long span and a contiguous short span. If you can, visualize that crossing. On the south side the anchors are an average of probably 80 ft. from what is called South Tower. Then comes the long span of 4427 ft., then a span of 1350 ft., and then a final span of 335 ft. to the other set of anchors. On the high tower between the 4427-ft. span and the 1350-ft. span, was placed a saddle with a sliding top. This was to allow for a difference in expansion between the two spans and to insure a vertical reaction on the tower. We calculated by a number of methods, but chiefly we went back to the original hyperbolic functions, and we thought that, taking all things into consideration, we might expect a possible travel of 5 in. We allowed for a travel of somewhat more than that, 8 in. being the final figure allowed, 4 in. in each direction.

The saddle was placed on roller bearings which were immersed in grease so as to offer the very freest possible travel for the cable. The operating department tells me that in the past year, according to the marks on the saddle, there has been a travel of only 1 in. so it is questionable how successful our calculations were. There is still room for improvement in our methods of calculation for long and important spans.

M. T. Crawford: I find Mr. Smith's paper very interesting in that he has gone into unequal supports, something which seems to have been more or less avoided in considerations of span problems. I would ask if he could suggest a method of approach toward the solution of a problem that we have. At one previous Pacific Coast Convention, a paper[2] was presented describing transmission-line construction in crossing Stampede Pass in the Cascade Range, where the loading conditions were very extreme at certains times of the winter, and where it was found advisable on account of the unequal loading which would come alternately on successive spans to change all dead-ends to a suspension form of conductor support, doubling up the insulator springs with yoked attachment at the suspension point.

The changes described in the previous paper have proved eminently successful in eliminating the operating troubles we had of jerking insulator strings in two. In trying to calculate the sags which would result from unequal loading in successive spans, we found a complication came into the matter where an entirely suspension form of construction was used, and where the towers were at different elevations, in that heavier loading in one span would pull the suspension strings out of the vertical position. This would make a change in the length of conductor in the span, location of points of support, and other factors, which are assumed constant in most of the ordinary methods of approaching the subject.

We worked it out fairly closely by making assumptions and trials, but found that the extreme condition which we might assume would occur when the insulator string was pulled out to a position approximately tangent to the catenary. This would result in the wire being down in the snow in winter conditions, but we have never found in practise that it went that far, because there was always some tension in the adjoining spans which would prevent the strings from pulling that far out.

I would like to have Mr. Smith add some discussion or suggestions as to how we might approach the problem of calculating the result of extremely unequal loading in the successive spans where the suspension form of construction is used.

G. S. Smith: I would like to thank Mr. Wood for mentioning a point I did not have time to bring up in the presentation and perhaps did not make clear in the paper, that is, that the method presented was intended primarily for long spans or special problems. It would usually prove too laborious for a single short span. However, where the Kirsten method is applied to the various symmetrical spans encountered in the usual line, it requires only a small amount of additional work to compute, by the method presented here, the remaining spans whose supports are not at the same elevation, since the cable used is commonly uniform throughout.

In discussions by Dr. Magnusson, Professors Kirsten and Sorenson, a more general use of hyperbolic functions was advocated. My experience has been somewhat similar to the instances mentioned. While most of us are more or less reluctant to use hyperbolic functions freely, I believe it is largely because of two reasons: first, we have never become accustomed to thinking in terms of such functions, and second, in attempting to use them we find it difficult because so few good tables of hyperbolic functions are available. In some previous work in connection with transmission-line design, I found it necessary to compute sufficient tables for this particular use. These tables will be found in one of the University of Washington Experiment Station bulletins referred to in the paper.

Messrs. Corbett and Crawford pointed out some very interesting problems in this same connection, problems which might be termed those of "variable spans." A similar problem was encountered in the design of "The Narrows" span of the Tacoma Lake Cushman Project mentioned in this paper. It was in an attempt to apply the Kirsten method to such problems that I found it desirable to first work out the problem of spans with supports at unequal elevations. Thus far I have found no direct method of attacking such problems, but the possibility of finding such a method seems entirely feasible.

The Long Span Across The Narrows at Tacoma

BY J. V. GONGWER[1]
Non-Member
and
A. F. DARLAND[1]
Associate, A. I. E. E.

THE double transmission lines now being built by the City of Tacoma, as part of its new Cushman Power Development, connecting Power House No. 1 and No. 2 (future) with the Cushman Substation in Tacoma, reaches 44 mi. from the North Fork of the Skokomish River in the foot hills of the Olympic Mountains around Hood Canal, across North and Henderson Bays, and over The Narrows to Tacoma.

The crossings at North and Henderson Bays are over shallow water, permitting of the installation of off shore towers, thereby materially reducing the length of spans that would otherwise have been necessary at these two crossings. Plans and profiles of the crossings at North and Henderson Bays showing the length of spans and the general features of the design are demonstrated herein.

Over The Narrows is being constructed what is believed to be the longest aerial span in the world, for the purpose of the transmission of electrical energy. The Narrows is a channel approximately 4800 ft. wide from shore to shore, 40 fathoms deep at the point of greatest depth, with a bottom strewn with large rocks. The entire tide run of lower Puget Sound must pass through this restricted channel, the current attaining a velocity of approximately 10 mi. per hour.

The use of submarine cable was never seriously considered for the crossing of The Narrows because of the danger of injury to cable by abrasion over the rocky bottom in the current of the ever changing tide, and further, because it would have been necessary to locate a step-down transformer station on the west side of The Narrows to reduce the line voltage from 110 kv. to a voltage at which submarine transmission can reasonably be expected to offer dependable service, at present probably not in excess of 50 kv. Both the initial and operating costs for the submarine crossing would be considerably in excess of those items for an aerial span.

An all-land line, avoiding the crossing of The Narrows, would, of necessity, have skirted the radial waterways of lower Puget Sound by way of Shelton and Olympia, a distance of 64 mi., 20 mi. longer than by the line of way of The Narrows, and through a district where a transmission line right-of-way would have been considerably more costly.

The natural conditions at The Narrows are very favorable for an aerial span, there being a high bluff on both sides of good bearing soil on which to locate supporting towers and cable anchorages, although the high ground is well back from the water's edge, requiring a single span of 6241 ft. 6 in. in order to take advantage of the tower sites.

CHOICE OF CONDUCTOR

The strength, size, and electrical characteristics of the conductor used are, to a large degree, the determining factors in the supporting tower and anchor design and considerable study was given to its choice.

Three general types of conductor cables were considered, viz: all steel, steel core with an aluminum envelope, and steel core with a copper envelope. Two circuits were to be built across The Narrows to operate at 110 kv., with grounded neutral, each circuit to be of sufficient capacity to carry 300 amperes under normal conditions and 600 amperes in the event that one circuit might be out of service and the entire load thrown on the other. The Narrows being a navigable body of water, the War Department required that a conductor clearance of 200 ft. above high tide be maintained. The Washington state laws governing electrical construction specify that transmission lines shall be designed to withstand a wind load of 8 lb. per sq. ft. on the projected diameter of the conductor when incased with ½ in. of ice, at a temperature of zero deg. fahr., and under these conditions shall have a factor of safety on the ultimate strength of the conductor of not less than two.

The inherent objection to a steel cable as a conductor arises because of the high electrical losses and the resultant heating in the cable which seriously impairs its strength if the temperature of the conductor is permitted to exceed the temperature at which the annealing of high strength steel begins. This temperature is quite generally agreed upon by steel cable manufacturers as being approximately 400 deg. fahr. if that temperature is maintained for long periods of time.

Concentric cable has the advantage of having more cross sectional area of material for a given diameter than any other form of stranding, thus presenting less diameter to the wind and offering less surface for the formation of ice for a given strength of cable. The electrical losses of such a cable may be minimized by reducing the size of the individual strands to the least practical diameter and reversing the direction of the spiraling of the successive layers.

Tests to determine the losses and heating were conducted on two samples of cable, each one inch in diameter and composed of 37 strands of galvanized steel having an ultimate strength of 195,000 lb. per sq. in., as a cable, after the galvanizing and stranding operations. One sample had all strands spiraled in the same direction, and the other had the successive layers spiraled in the opposite direction. These tests indicated that at 300 amperes, the normal full load of each

1. Both of the Cushman Power Project, Tacoma, Wash.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash. Sept. 15-19, 1925.

transmission line, the electrical losses in the cable having the reverse lay were only 60 per cent of the losses of the uniformly spiraled cable. Thermometer readings of the surface temperature indicated that even with the reverse lay cable to carry 600 amperes of current in one transmission circuit, using steel cable of the required strength, a diameter of at least 1¼ in. would be required to insure that the annealing temperature would not be dangerously exceeded.

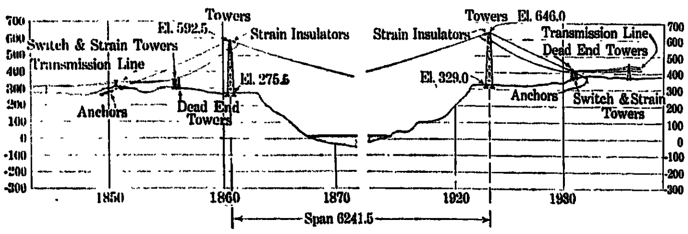

Fig. 1—General Diagram of Crossing

A 1¼ in., 35-strand, specially constructed, concentric, reverse lay steel cable having an ultimate strength of 180,000 lb. after galvanizing and stranding was chosen as offering the greatest economy in the first cost of the complete aerial crossing and its subsequent operation.

Circuit Arrangement

The general design of the crossing is shown in Figs. 1 and 2. The conductors are arranged in a horizontal plane 30 ft. between phases and 120 ft. between the two circuits. The four main towers are each 316 ft. 6 in. high from the tower footing to the point of cable support at the top of the tower and are of the simple prop type. The conductors proper terminate at a nest of 12 multiple strings of high-strength suspension insulators, each string consisting of 11 units, equalized by means of springs to insure the proper mechanical loading of the individual strings, and the entire assembly attached to the supporting cables which pass over large sheaves on the top of the main towers and thence down and back approximately 900 ft. to anchors imbedded in the earth.

Jumper cables of copper attach to the steel conductors of the long span on the water side of the main towers and are carried through and around the latter back to switching towers near the main cable anchors. Disconnecting switches are provided here to isolate either crossing circuit and to multiple the transmission lines through one crossing circuit, or if necessary any three of the six conductors crossing The Narrows may be selected for a circuit and tied in with both transmission lines.

General Structural Design

To reduce maintenance cost, and to attain the utmost dependability in service, simplicity of design was sought in all features.

Investigations were conducted over a period of several years and such information gathered as was available concerning similar installations, notably the crossings of the Pacific Gas & Electric Company and of the Great Western Power Company over Carquinez Straits, the Knoxville Power Company's crossing over the Little Tennessee River, and the crossing of the Shawinigan Power Company over the St. Lawrence River. Considerable correspondence was carried on and some interviews were had with the engineers and officials of the companies mentioned.

In the design of towers, foundations, and anchors it was possible to proceed along the lines of standard practise. Matters concerning the strength and other characteristics of cables—fittings and insulators—are now also fairly well established. However, the question of the behavior of this equipment under service similar to that proposed opens up a large field for discussion and research, probably the most troublesome consideration being the matter of vibration in long suspended cables.

It was desired to avoid, so far as practicable, all undesirable features affecting upkeep and continuity of service as experienced in similar installations.

It was early decided that a messenger span with 1⅜ in. concentric strands, working at a factor of safety

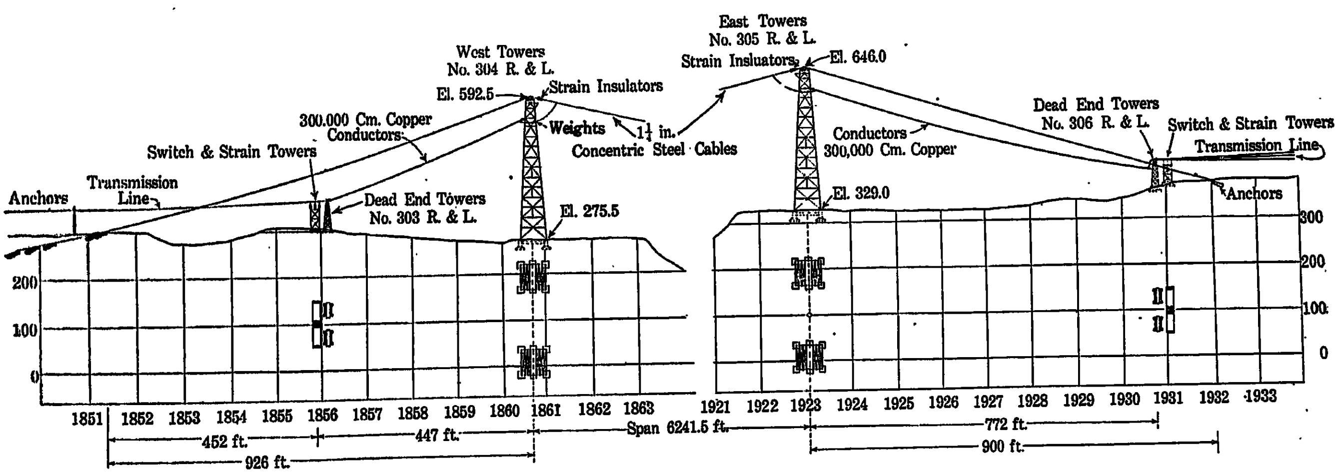

Fig. 2—Elevation and Plan of Crossing

of two and supporting separate conductors, would be the most desirable arrangement, the suspension insulators to be placed at irregular intervals to damp vibration. Further study, however, led to the final adoption of 1¼ in., 35-wire concentric steel strands, acting as self supporting conductors, using a factor of safety of three based upon the ultimate strength of the strand, and supplying at the supports and anchors devices in the way of fittings and relieving cables which would minimize the stresses and effects set up by vibration.

The combination of devices adopted are believed to be novel, but some of these features have been suggested by similar installations.

It has been the aim throughout, wherever indeterminate shocks and variations of stress are to be expected, to provide such ample factors of safety as to remove all possibility of failure from these sources.

Economical Considerations Affecting Sag and Tower Heights

The factor of safety to be provided in the cables having been decided upon, comparative estimates were prepared, based upon various cable sizes, and the corresponding sags, tower heights, anchors, etc.

The costs of cables, and fittings, towers, and anchors were interdependent and must be computed as a whole for each design.

It was found that, as size of cables and consequently tower heights and anchorages were varied within practicable limits, the total cost of the complete crossing remained comparatively fixed.

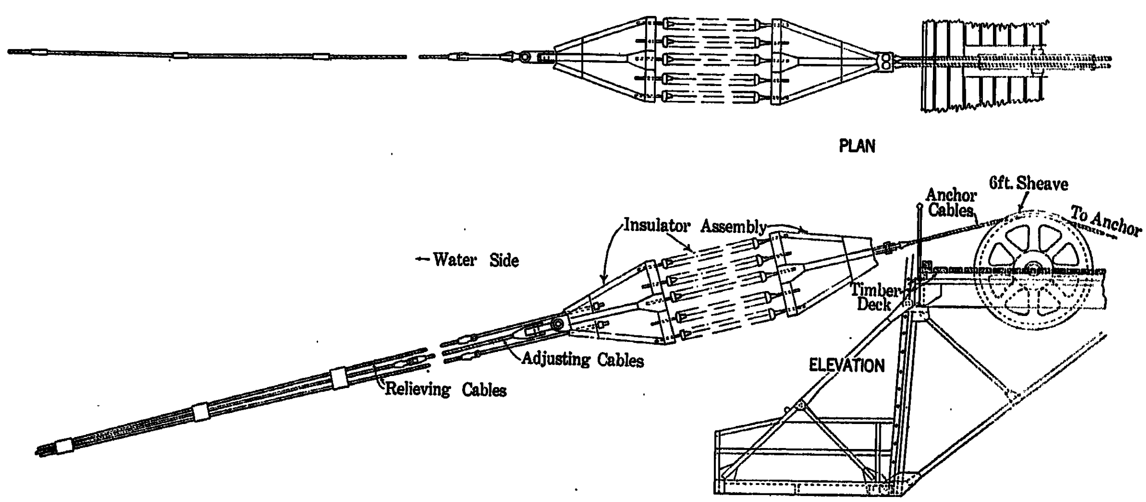

Fig. 3—Showing Assembling of Insulators

It was therefore decided to base the design upon 1¼ in. cable, as being the smallest size that would satisfy electrical requirements.

As to possible necessity for replacement, it is interesting to note that some of the cables of the Pacific Gas and Electric Company's span, under similar conditions, have been in continuous service for 24 years, with an unknown length of useful life still remaining. Examination of one of these cables showed the outside wires to be only slightly deteriorated and the interior wires to be in perfect condition, with galvanizing unimpaired.

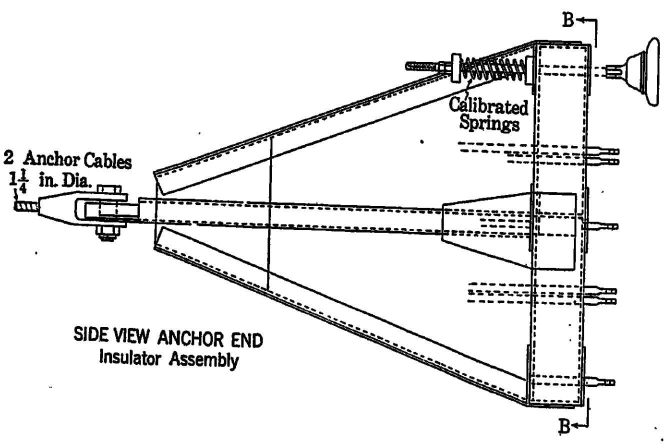

Fig. 4

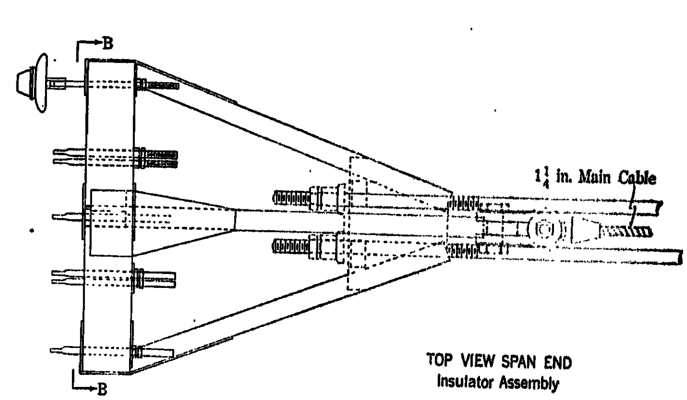

Fig. 5

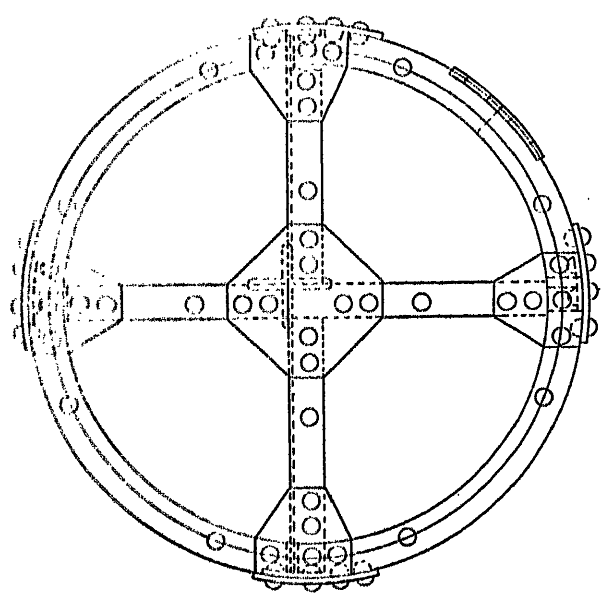
Cables and Fittings

The cables for this crossing will be 1¼-in., 35-wire, galvanized strand, consisting of acid, open hearth, plough-steel wire. The net area of steel in the strand is 0.93 sq. in., and it will weigh approximately 3.25 lb. per linear foot.

The guaranteed ultimate breaking strength of this strand is to be 180,000 lb., and tests already carried out show strengths well over this figure. Each coil of galvanized wire going into the make-up of the cables is being tested, the breaking strength running between 210,000 lb. and 220,000 lb. per sq. in.

Under maximum loading of ice and wind, the working stress in the cables was taken at 60,000 lb., affording a factor of safety of three, and the corresponding sag for determining clearance at 32 deg. fahr., when laden with ice, will be approximately 397 ft., with a stress of 56,500 lb. Stringing stress at 70 deg. fahr. would be about 43,000 lb.

The main cable, considering one cable only, is attached by an open socket and clevis to the front of the insulator assembly, as shown in Fig. 3. One 90-ft. and one 70-ft. relieving cable will extend out from insulator assembly along the main cable. The outer ends of these relieving cables are to be securely served to the main cable and also attached thereto by a series of evenly spaced U-bolt clamps of cast steel. While these clamps are being attached, the relieving cables will be stressed in successive increments by means of the long threaded eye-bolts attached to front of the insulator assembly, in order to put the same amount of stress on each clamp.



SECTION BB

Fig. 6—Cross Section of Insulators

From the back of the insulator assembly, two anchor cables will pass over the sheaves and attach separately to evener at front of anchorage by means of adjustable bridge sockets.

The purpose of the relieving cables, with their load of clamps, is to reduce stress in the main cable and damp vibrations, while the two anchor cables give double strength where passing over the sheaves and facilitate replacements or take-up.

All cables are identical, except that the main cables are reverse lay, while relieving and anchor cables are ordinary lay.

Insulator Assemblies

The question of insulation appears to be adequately solved by the design of insulator assembly adopted, see Figs. 3 to 6. This consists of two rigid steel frames or yokes, conical in general form, and constructed of light channels, angles, and bent plates.

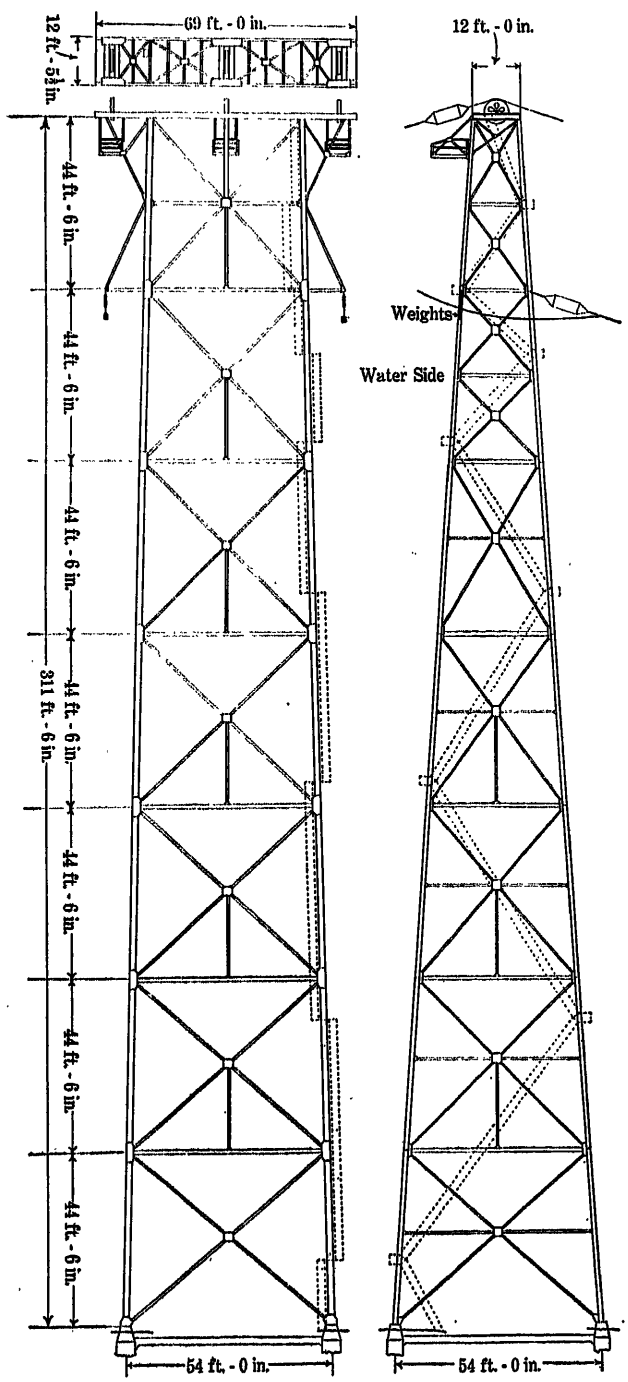


Fig. 7—Side Elevation of Tower

Between these yokes are placed twelve strings of high

strength suspension insulators, eleven units to the string. The minimum ultimate strength of these units is 18,000 lb. while the working stress will be 5000 lb., which closely parallels the conditions of service found to be satisfactory on the span of the Great Western Power Company.

The two yokes are identical except as to the arrangement for cable attachment.

Calibrated springs are provided at the rear end of each string to equalize stress and assist in eliminating shock.

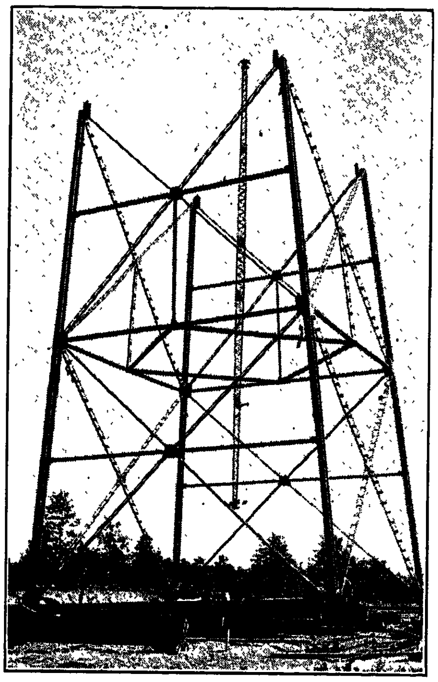

Fig. 8—Erecting Tower with Floating Gin Pole

With this rigid form of yoke, the breakage of any string would only slightly unbalance the loads carried by the other strings and a broken unit may be replaced and the string brought up to the proper working tension by means of the eye-bolts and springs.

During erection the insulators may be replaced by steel rods.

Towers

The towers are rectangular in form, 54 ft. square at the base, in which least number of members and ease of erection were considered together with economy of material; see Fig. 7.

Although the foundations on one side of the crossing are 53½ ft. higher than on the other side, it was decided to make the four towers of the same height, and identical in all respects.

The towers are 313 ft. from top of concrete to top of deck girders, consisting of seven 44-ft., 6-in. panels plus the depth of the 18-in. deck girders. The sheaves and bearings add another 3 ft. 6 in., making the total height from top of foundations to point of cable support 316 ft. 6 in.

The maximum computed reaction at base of the columns is 310,000 lb. and the greatest uplift 89,000 lb., the greatest stress in any of the diagonals being 33,500 lb.

Due to the importance of the structure as a vital link in the transmission line, and due also to legal regulations, the following conservative working stresses were adopted:

	Lb. per sq. in.
Tension:	
Rolled Steel	18,000
Bolts (net area)	12,000
Bearing:	
Pins, Shop and Field Rivets	20,000
Shear:	
Web Plates	10,000
Pins, Shop and Field Rivets	10,000
Extreme Fibre Stress:	
Rolled Steel Shapes	16,000
Rolled Steel Pins	20,000

Columns or Struts Axially Loaded:

Working stress not to exceed 18,000-701/r, and not to exceed 14,000 lb. per sq. in.

Slenderness Ratio 1/r:

Not to exceed 120, except for bracing and members resisting wind only, where 1/r is not to exceed 150.

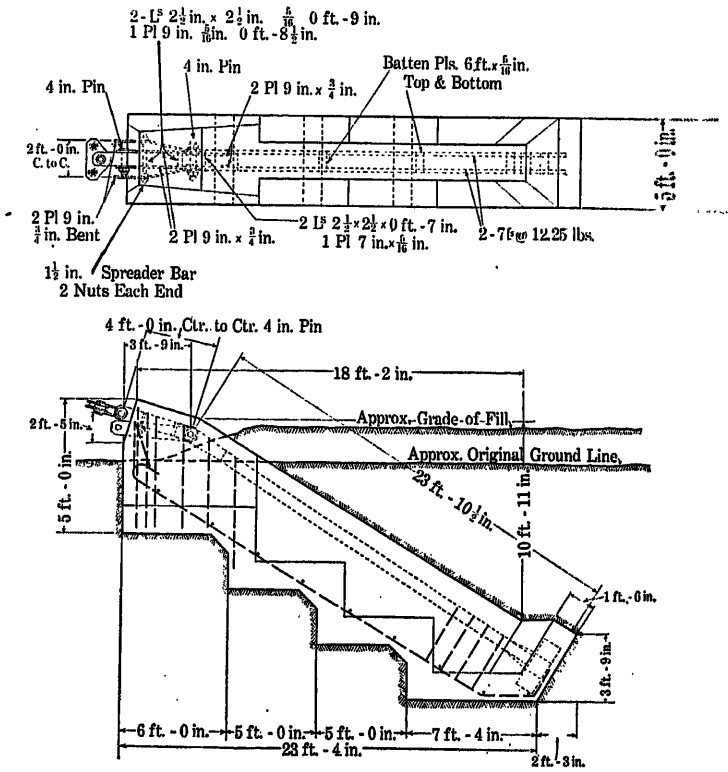

Fig. 9—Plan and Elevation of Anchor

A wind pressure of 20 lb. per sq. ft. was assumed on the projected area of all steel members.

The details of the towers are notable for the entire absence of latticing.

For economy of material, accessibility for painting,

and other considerations, the familiar built-up type of column was selected, consisting of an I-beam and two channels, the largest section being one 12-in. I of 31.8 lb. and two 12-in. [s of 30 lb. at the base of the tower, and one 9-in. I of 21.8 lb. and two 8-in. [s of 13.75 lb. for the upper sections. The lower diagonals are two [s 3½ in. by 2½ by 5/16 in., battened. The minimum thickness of metal used is 5/16 in., with possibly a few minor exceptions.

For a slight additional cost above that of a simple ladder, a light stairway with convenient landings is provided on each tower.

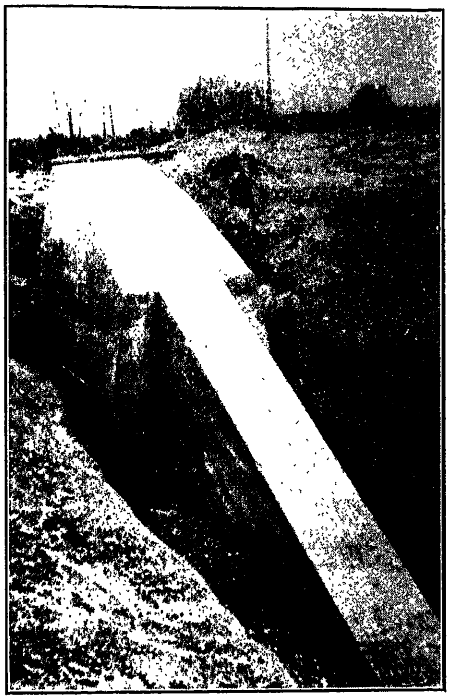

Fig. 10—Completed Anchor—Back View

Platforms extending out under the strain insulator assemblies facilitate inspection. These platforms are pin-connected to the main structure and can be swung down out of the way if desired at any time. The hand rails surrounding the platforms are also easily folded flat on the deck.

The total weight of each tower is 260,000 lb.

Tower Footings

The footings consist of simple concrete stepped footings, 12 ft. square, surmounted by 5-ft. square shafts. Four 2⅜-in. anchor bolts are embedded therein, extending to a steel plate 12 inches above the bottom of the footings. The footings are carried to a minimum depth of 9 ft. 6 in. below finished grade of the sites and are connected just below grade by 18-in. by 24-in. reinforced concrete struts.

Anchorages

From several preliminary designs, a somewhat novel type of cable anchor affording a large factor of safety and eliminating any apprehension from this feature of the structure was decided upon. (Figs. 9 to 11.) The lower faces of the anchors are stepped and the entire excavation is in firm compacted gravel, which gives them a power of resistance which is impossible to calculate with accuracy, and provides a large margin of strength for any possible future requirements.

The structural steel members to which the anchor cables are attached are carried to the extreme back end of the anchors.

The steel eveners are so designed as to permit one anchor cable to be completed slackened off and removed without cramping the terminal socket of the other cable.

Extra eye-bars are provided for haul-back purposes.

Sheaves

Built up structural steel sheaves 6 ft. in diameter, with cast steel rims, were originally designed for the support of the cables, but one-piece cast steel sheaves have been since manufactured for this purpose, the castings being exceptionally perfect and free from flaws.

The shafts are forged steel 7 in. in diameter, turned down to 5 in.—where they rest in bronze bushed bearings.

Each sheave weighs approximately 5000 lb. Calculations indicate that variations in loading may cause these sheaves to rotate approximately 13 in.

Construction and Erection

The foundations and cable anchors were constructed during the winter of 1924-25 at a cost of $33,000, and the contract for the fabrication and erection of the main towers together with the switching towers and stringing of cables was awarded Feb. 16, 1925, to the Star Iron and Steel Company of Tacoma, at a contract price of $149,000, the towers to be completed by Sept. 19, 1925, and the cables to be strung by Oct. 19.

Fig. 11—Group of Anchors at East End of Cables

The contract for furnishing cables, fittings, and insulator assemblies was awarded Feb. 13, 1925, to the John A. Roebling's Sons Company, at a contract price of $37,600, delivery to be made Aug. 25, making the complete cost of the crossing $219,600.00.

Erection was begun on the switching towers May 21, and the first steel column of the main towers was set June 6th, and the erection is progressing rapidly.

A 90-ft. basket or floating gin pole is being used, suspended in the center of the tower by four sets of falls attached to the columns at the panel points, the top being controlled by four lines operated by hand winches attached to the 18-in. by 24-in. concrete struts between footings.

Upon the completion of each panel the pole is raised or "jumped" 44 ft. for erecting the next panel. This method of erection has been used on many of the radio towers constructed in recent years.

Cost of Development

The cost of the development of the first 50,000 h. p. of the Cushman Power Project will be approximately $5,000,000.00, and is being carried on under the general supervision of J. L. Stannard, Chief Engineer.

The authors wish to express appreciation of the courtesies extended by J. P. Jollyman and L. J. Corbett of the Pacific Gas & Electric Co., J. A. Koontz of the Great Western Power Co., Theodore Varney of the Aluminum Co. of America, and S. Svenningson of the Shawinigan Power Co. Limited. C. C. Sunderland of the J. A. Roebling's Sons Co. also rendered valuable service when the matter of steel cables was under consideration.

Discussion

G. S. Smith: I should like to ask Messrs. Gongwer and Darland if any provisions are being made to obtain data on the cable movement over the two main supports? This could easily be accomplished by means of a graphic instrument to keep a record of the sheave movement, together with temperature. A record of the wind velocity and its direction, as well as a log of ice loading or other unusual conditions, would be very desirable.

The slow movement of the cable over the supports due to the temperature or loading changes, as well as the vibrations which may take place, would make a very interesting study in this unusually long span.

Such data would be highly instructive from the standpoint of investigation and future design, and might also prove valuable from the standpoint of maintenance.

G. R. F. Nuttall: I should like to bring up a point in connection with cables for long crossings. In our own transmission lines we have had to go into the details of sag calculations, and in all cases it is necessary to make quite a number of assumptions to start with, particularly in connection with cables which are formed of two different metals, aluminum and steel, for instance, where the combined modulus of elasticity and coefficient of expansion of the two metals has to be taken into account.

Have any of the cable manufacturers made any experiments with cables having a layer of aluminum strands on the outside, then a layer of strands—the modulus of elasticity and coefficient of expansion of which lie between those of aluminum and steel—and within the center the usual steel core? This would offer a more homogeneous cable in which the relative movement between layers would be less likely to occur.

R. J. C. Wood: For our use we have developed a dynamometer which is essentially a steel rod some 20 in. long, and we measure the extension of that rod under load with an ordinary dial extensometer.

L. J. Corbett: In this paper the point which I noticed particularly was the test of the two types of cable—that with the concentric layers oppositely wound and that with the layers wound in the same direction. The Pacific Gas and Electric Company long ago adopted for Carquinez the cable in which the layers are wound in the same direction, with the idea of getting greater strength for a given weight. This method produces a very compact strand, and this was the controlling feature in the selection of the cable. A new point is brought up when tests showed a difference of 60 per cent in resistance. This is certainly well worth considering.

A. F. Darland: Mr. Smith has brought up the point of keeping a record of the movement of the cable over the sheave on the Narrows crossing. We have computed the probable movement we shall get, and expect probably a foot. No definite means has been provided at this time to keep a record of that movement, but it will undoubtedly be noted and recorded. We have a calibrated spring on each string of the high-tension insulators whereby we may know the tension in the cable, and we shall in addition keep an accurate record of the sag, measuring it with a level.

220-Kv. Transmission Transients and Flashovers

BY R. J. C. WOOD[1]

Associate, A. I. E. E.

Synopsis.—*The conclusion has been reached that birds are the cause of flashovers on the Southern California Edison line. The frequency and location of flashovers is given for nine years of operation at 150 kv. and two years at 220 kv. The increase in the number of flashovers when first going to 220 kv. has been reduced so that now there is no greater number than there was at 150 kv. This has been done by installing bird guards which are, however, not yet completely bird proof. Other possible causes of flashovers are considered, including corona, standing and traveling waves of high voltage, harmonic resonance, sustained high-frequency effects, lightning, and highly ionized air. Investigations to discover the presence of such disturbances are described; they included the use of a homemade photographic surge recorder, the klydonograph, and oscillograph. The amplitude of voltage surges caused by various switching operations and the quantity of tertiary and residual current at the different stations on the system are tabulated.*

The conclusions reached are that there are not any voltage disturbances of greater magnitude than those produced by normal switching, and that such voltage rises as do occur are totally inadequate to cause flashovers or cause any damage to connected apparatus. The evidence is all against the existence of sustained high-frequency currents or voltages and it may be stated confidently that they do not exist.

* * * * *

FLASHOVERS

THE more or less occasional flashovers on the Big Creek Transmission System of the Southern California Edison Company have been the subject of study for several years in the effort to find their true cause, but none of those who studied this problem could find an electrical theory that would explain all the facts. Finally, a man unacquainted with mysterious resonance phenomena and dire high-frequency potentialities observed the one fact that had escaped the rest of us, and, as H. Michener describes in his paper[2], the bird theory was evolved. This theory, that flashovers on this system are due to the excrement of birds falling through the air and affording a conducting path between conductor and tower, is now firmly established and believed by those on the ground.

The frequency of these flashovers from January 1, 1914 to July 31, 1925 is shown in Fig. 1, the voltage of the line being 150 kv. prior to May 6, 1923 and 220 kv. thereafter. The immediate increase of flashovers is noticeable when the raise in voltage increased the size of the bullseye which the bird had to hit in order to score. It will also be seen that since the installation of various kinds of bird guards, which was done mainly during the last half of 1923, the occurrence of flashovers has been of about the same frequency as during 150 kv. operation.

When it was first determined to put on bird guards, two factors were underestimated: first, the lateral distance from the center line of the insulator string from which a roosting bird could cause a flashover when the wind was in the right direction to carry the stream of excrement into the vicinity of the conductor, and secondly, the bird's intelligence. He had used that tower for a roost and observation point for years and looked upon any effort to oust him as an invasion of his rights, and he proved quite clever in surmounting the difficulties first put in his way.

In the winter months of 1924-25 observation on the line showed that the birds, prevented from roosting on the more accessible parts of the tower, were accommodating themselves to new conditions and getting in on secondary members of the steel work that it had at first been considered unnecessary to guard, so that the line is not yet fully equipped with absolutely bird proof devices and the flashovers still occurring have in each case been traced to imperfect bird guards.

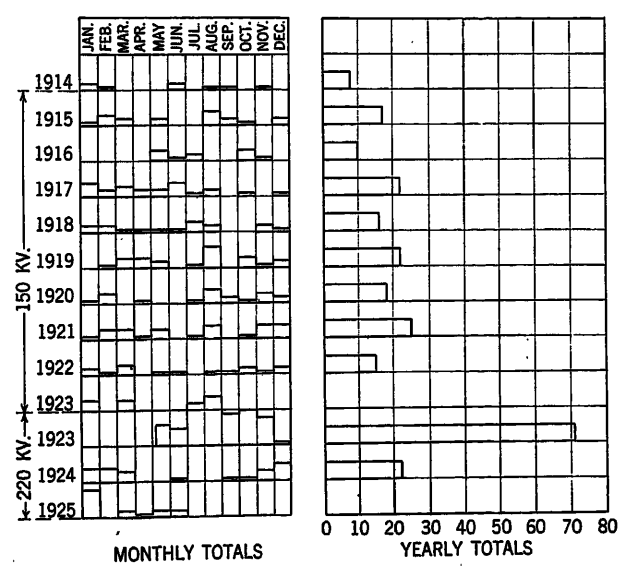

FIG. 1—RECORD OF THE NUMBER OF FLASHOVERS ON BIG CREEK LINES; TOTALS BY MONTHS AND YEARS

The commercial significance to service of the flashovers has become a vanishing quantity now that reliable automatic relays are in use, provided duplicate sectionalized lines are available which will not be overloaded upon the loss of a section. The effect of a flashover upon received voltage and frequency is shown in Fig. 2, and is seen to be inconsiderable and momentary.

The space distribution of flashovers along the line is given in Fig. 3; the remarkable similarity between the distributions for 150-kv. and 220-kv. operation is at once apparent. This in itself is significant of no new

1. Research Engineer, Southern California Edison Co.
2. Transmission at 220 kv., Section 1, by H. Michener.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash. September 15-19, 1925.

factor having arisen with the increase of voltage; in fact, it is very evident that the tendency to flashover chiefly depends upon the location of the insulator along the line.

Possible Causes of Flashovers

Considering other possibilities than birds, the exciting cause of flashovers might be either internal, such as standing or traveling waves of abnormal voltage, or sustained high-frequency capable of breaking down relatively large air spaces, or external, such as lightning or highly ionized air.

The three horizontal conductors are asymmetrical with regard to the ground wire so that the outer conductor most remote from it should suffer most from lightning disturbance. During 150-kv. operation, 66.3 per cent of flashovers were on the middle conductor;

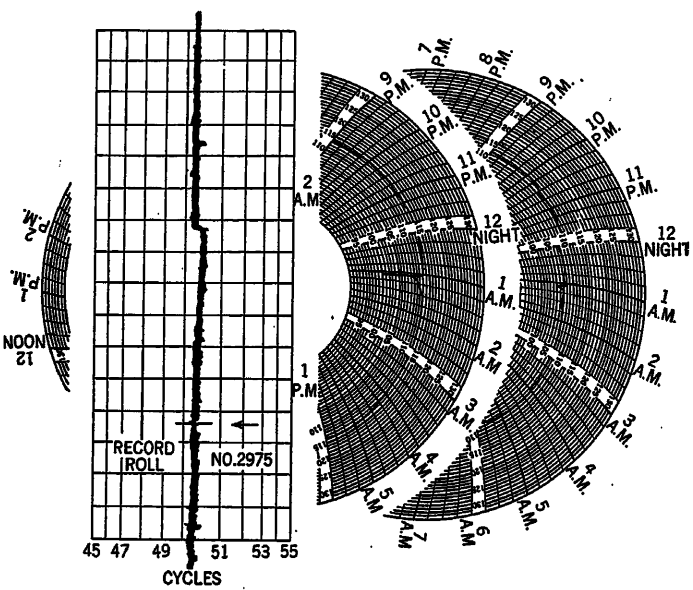

Fig. 2—Disturbance Caused by Flashover. to System Frequency and Voltage at Two Kv. Substations

after going to 220 kv. this percentage increased to 88.5 per cent.

Evidently, no distributed atmospheric effect is responsible. This eliminates ionized air and lightning, especially since practically all of the flashovers have occurred when there was no lightning.

The possibility or otherwise of internal disturbance is not so easily disposed of, and in an effort to clear up this question a few investigations were undertaken.

Corona

It has been suggested that corona on the arcing horns of the old 150-kv. equipment might be a starting point for the high-frequency streamer, in fact, that the least bit of corona was a dangerous thing to have around. In November 1921, hollow copper balls, some 3-in. and some 4-in. diameter, were put over the ends of the arcing horns on the middle conductor of the East Line from mile 105 to mile 163 where, as may be seen in Fig. 3, flashovers were above the average in frequency. These balls suppressed the corona, did not decrease the arcing distance, and improved the voltage distribution of the insulator string, but the three next flashovers in that month and three out of four in December were over ball protected insulators. Evidently, corona was not the cause of the breakdowns.

Photographic Surge Recorder

At the time these matters were being studied in 1921,

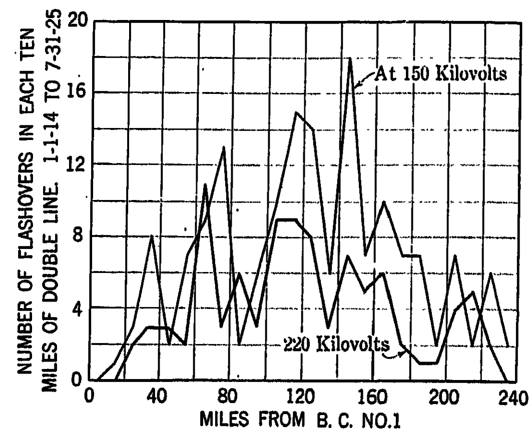

Fig. 3—Space Distribution of Flashovers Along Line

preparatory to increasing the line voltage to 220 kv., there did not appear to be available any commercial voltage surge recorders that were suitable to our purpose, so we combined a kodak film with the clockwork mechanism of a curve drawing wattmeter, and there resulted a somewhat crude daylight loading surge recorder using standard 3A film.

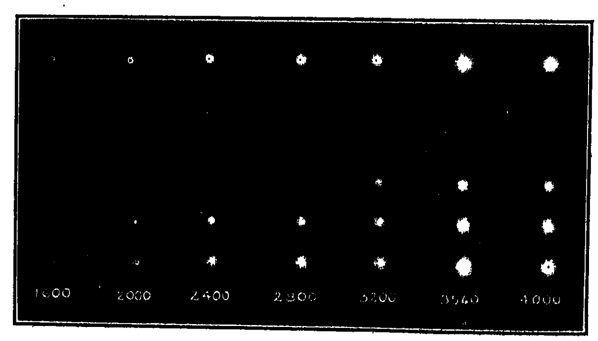

Fig. 4—Calibration of Surge Recorder on A-C. Voltage

Six hemispherically-ended metal wires, together with a grounded metal drum, formed six spark-gaps of different lengths through which the film passed. The spark-gap terminals were all connected in parallel across the ground-end unit of a string of insulators hung from the line under test, and so shielded as to provide a suitable voltage for the recorder. The parallel gaps broke down successively at increasing voltages as long as the insulating celluloid film was in them, as shown in Fig. 4, which is a laboratory calibration using a-c. voltage. The film was driven by a weight-actuated mechanism, the

clock regulating the speed. The whole device was enclosed in a wooden box supposed to exclude light. One of the spark-gaps was used to mark time, being in series with a commutator that broke circuit every two hours and was driven by the same clock that regulated the film speed. The instrument is shown in Fig. 5.

This instrument was in use on the Eagle Rock 150-kv. bus for three months and was then installed at Vestal. A record obtained by its use is shown in Fig. 6. The broad band at the left is the discharge from the

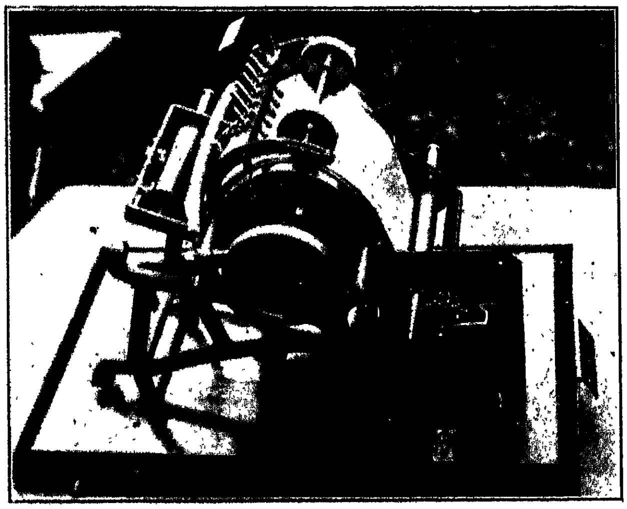

Fig. 5—Photographic Surge Recorder

first gap which was set at just below normal voltage, the second gap went over at approximately 1.25, and the third one at 1.50 times normal voltage. The right hand band is from the timing point working indifferently well.

It was the general rule to kill the bus before admitting

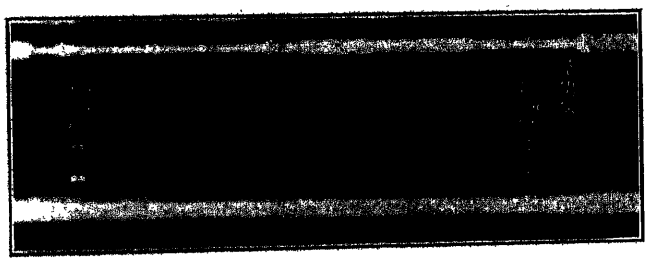

Fig. 6—Surges Recorded at Eagle Rock on 150-Kv. Bus

any one to the bus compartment for the purpose of changing films, and it was soon found that this station switching caused the highest voltages that were recorded, none of which, however, exceeded approximately double normal. The recorder was in operation upon the 150-kv. bus at Vestal after the line had been raised to 220 kv. but was never installed directly upon the 220-kv. line. It had satisfied us that there were no voltage surges on the 150-kv. system of anywhere near sufficient magnitude to cause flashovers.

This recorder suffered from many defects, largely of a mechanical nature; difficulty was encountered in getting the film to reel up smoothly on the receiving spool, and considerable fogging of the film took place when installed out of doors from leakage of light through the containing wooden box, the time-recording device was imperfect, and the indications were not at all

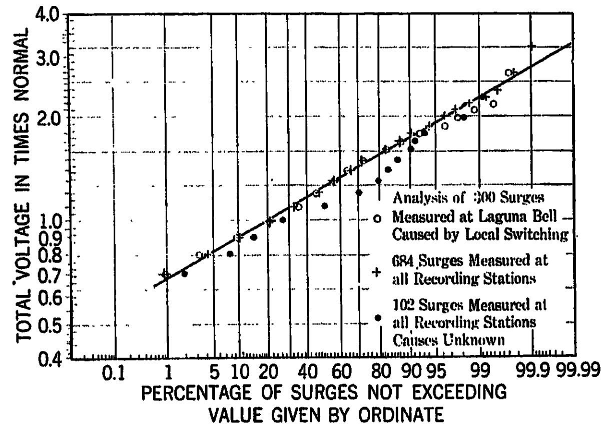

Fig. 7—Relative Percentage of Voltage Surges of Different Amplitudes

precise, increasing as they did by 25 per cent steps. Still it worked after a fashion and indicated conditions that have since been confirmed by more perfect apparatus.

Klydonograph Tests

Some time later, the Westinghouse Electric Company brought out its Klydonograph[3] surge recorder in which

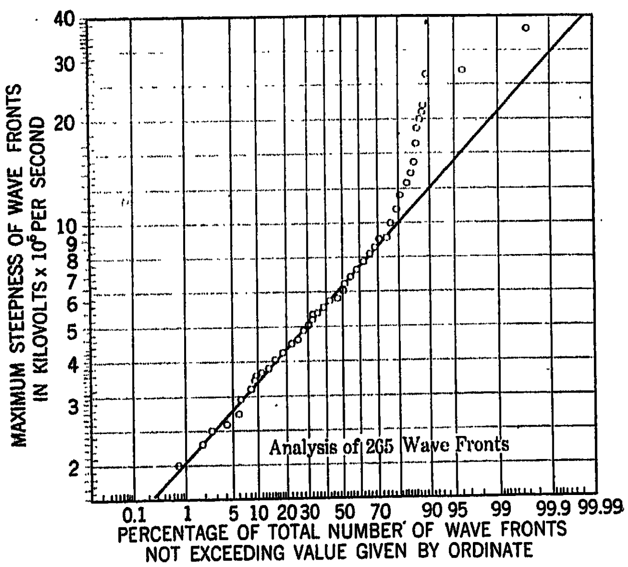

Fig. 8—Relative Percentage of Wave Fronts of Different Maximum Steepnesses

only one recording point is used and the magnitude and character of the voltage estimated from the size and nature of the picture produced. Through the courtesy of the Westinghouse Co., installations were made at Big Creek No. 1, Vestal, Magunden, and Laguna Bell.

3. The Klydonograph and its Application to Surge Investigation, by J. H. Cox and J. W. Legg.

These installations were in service 89 days at Big Creek No. 1, 75 days at Vestal, 71 days at Magunden, and 119 days at Laguna Bell. There were 684 indications of voltage rise and 556 indications of wave front slope recorded. More than a normal amount of switching was being done at the time as one line was taken out of service every night to reduce losses. The approximate number of oil-switch operations performed on the 220-kv. system averaged over 36.3 per day and about 18 daily oil-switch operations were made on the 150-kv. station busses which are conductively coupled to the 220 lines through auto-transformers. The average total number of surges per day was 8.71. The ratio of number of surges to switchings is 24 per cent if only the 220-kv. switching is considered and only 16 per cent if the 150-kv. switching is included.

The relative percentage of abnormal voltages of different magnitudes is shown in Fig. 7 plotted upon probability paper. The very close conformity of the plotted results with a straight line indicates both that a sufficient number of observations were obtained to get representative results, and also that no particular predominating cause exists that is responsible for surges of any particular value.

The curve for surges measured at Laguna Bell, due only to local switching operations, is practically coincident with the curve of all causes for the whole of the system. From this we may conclude that the magnitude of the voltages resulting from normal switching operations was, on an average, independent of the location of the switching.

The surges of unknown origin which could not be correlated with switching on the 220-kv. system average of lesser magnitude.

The steepness of wave fronts is shown in Fig. 8. In this case the probability law is followed up to wave fronts of about 10×10^6 kv. per sec. Above this value results are erratic. This is explainable by the fact that the greater part of the observations between 2×10^6 and 10×10^6 kv. per sec. were obtained at Laguna Bell as the result of a great number each of a number of different switching operations, whereas the steeper slopes were observed at Vestal and Magunden and are inherent to a few particular operations at those stations. The curves therefore seem to indicate that slopes of wave fronts originating at different stations are of different orders of magnitude, whereas the amplitudes of potential surges at different stations are of the same order. It may be pointed out for comparison that the maximum steepness of normal 50-cycle sinusoidal waves at 220 kv. is 0.0564×10^6 kv. per sec.

The evidence as to the extent that surges are transmitted over any considerable distance is rather hard to interpret depending somewhat upon the definition of the word "surge."

A surge might be considered to have traveled:

1. When a voltage rise is due to switching at a distance
2. When antenna indications of current waves show them to have traversed certain distances
3. When records of voltage rise are found at two or more separated points all due to a common localized cause

TABLE I
TRANSMISSION OF VOLTAGE DISTURBANCES

Recording Station	Number of Disturbances Recorded at			
	Laguna Bell	Magunden	Vestal	B. C. No. 1
Total Number recorded......	402	38	17	41
Number originating at Laguna Bell and also recorded as shown....................	..	0	0	0
Ditto originating at Magunden	3	..	0	0
	2	..	0	2
Ditto originating at Vestal....	1	0	..	0
Ditto originating at B. C. No. 1	0	0	0	..
Ditto origin unknown........	1	0	0	1

It has been thought best to confine the evidence to that under heading No 3, as this required direct proof of the transmission of a voltage disturbance, while Nos. 1 and 2 do not necessarily do so. Such evidence is given in Table I and shows to what an insignificant amount such action occurs over the distances in question.

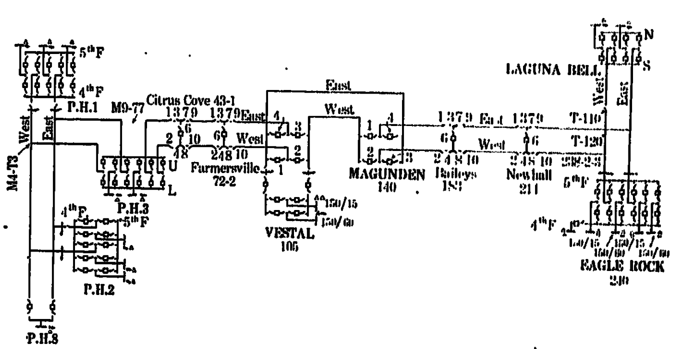

FIG. 9—SWITCHING DIAGRAM OF 220-KV. SYSTEM

The antenna instruments gave many indications of current rushes in the line without corresponding voltage records being obtained. Apparently there was not any definite relation between voltage amplitude and wave front steepness.

For those who care to analyze further, Fig. 9 presents a switching diagram of the system and Tables II and III show the different switching operations performed, together with the range of the resulting surges.

It should be noted that even though the disconnects at the main switching stations only make or break the charging current of a few feet of bus and one side of an open oil switch, that when so doing they cause voltage rises of as high a value as do other switching operations that involve 100 miles of line.

Some explanation of the meaning of voltage rises of less than 1.0 times normal is due.

The klydonograph actually records a measured fraction of the line voltage, an electrostatic potentiometer being used to effect this. Between the klydonograph and potentiometer is a sphere-gap adjusted to breakdown for a slight increase in line voltage and to give a corresponding size of picture on the photographic plate.

Records were occasionally found upon the plate corresponding in size to voltages less than the normal breakdown value of the sphere-gap, and these have been included in the tabulations, as found, as less than unity surges. The calibration of the photographic plate at these low voltages is somewhat uncertain especially when the duration of the surge is so short that only a few rays are formed in the picture and this is the probable explanation of pictures of a size less than corresponds to the series spark-gap. In any event these apparently subnormal surges are only of academic interest and have no bearing upon flashovers. At supernormal voltages the accuracy of the calibration is probably well within 15 per cent at twice normal voltage and better yet at higher voltages. Calibrations made at the factory, in the Southern California Edison laboratories and in the field, check very well and prove

FIG. 10—LINE VOLTAGE TO GROUND AT BIG CREEK NO. 3

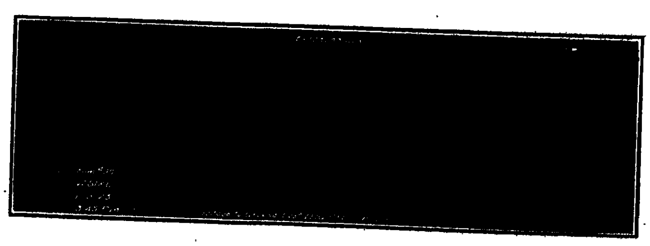

FIG. 11—LINE VOLTAGE TO GROUND AT VESTAL

that the obtaining of 0.7 times normal pictures does not mean that the whole calibration of the klydonograph is 43 per cent low.

TERTIARY AND RESIDUAL CURRENTS

To determine whether there were any abnormal residual, tertiary, or other odd harmonic currents or voltages, a number of oscillograms were taken, nothing

out of the ordinary being done except, perhaps, in obtaining oscillograms of line voltage direct without interposing potential transformers.

This was accomplished by using a 50-ft. length of ½-in. common garden hose filled with water as a resistance in series with the oscillograph element, with a precautionary shunt, in parallel with the element. No special difficulties were encountered except that in the

the hose. This difficulty was entirely overcome by having a small reservoir of water (old 5-gal. oil can) at the high-voltage and high-level end; this supplied losses

and kept the hose full of water. The current through the hose and oscillograph to ground varied from 37.0 milliamperes at Laguna Bell to less than 0.3 milliamperes at Big Creek No. 3, showing resistances of the 50 ft. of hose of 3.36 and 423 megohms respectively. This, it may be remarked parenthetically, is truly indicative of the relative difficulties in the two locations of obtaining good ground connections for transformer neutrals.

Efforts were also made to determine the crest voltage on the line by direct sphere-gap measurements putting the sphere-gap at the ground end of the 50-ft. hose full of water. The drop of voltage along the hose due to charging currents rendered the method useless and we had to be satisfied with the wave shape of voltage obtained as previously described.

The results of the investigations were negative so far as supplying any reason for flashovers was concerned. Third, fifth, and ninth harmonic currents were no larger than was to be expected, and voltage waves were apparently so nearly sinusoidal that we did not indulge in harmonic analysis.

Examples of the results are shown in Figs. 10 to 17 which are self-explanatory. Table IV gives a summary of the magnitude of tertiary currents and in Table V will be found the values of residuals to ground. These residuals are due to the impedance of tertiary windings, generator harmonics other than multiples of the third, unbalance of the lines which are not transposed, and possibility to slight transformer inequalities. Considering the magnitude of the system and the untransposed line, the residuals are small.

The search for abnormal and startling effects has been distressingly unsatisfactory from a spectacular point of view, but most reassuring to those who contemplate the use of high voltages for transmission. Not only have no unusual effects been discovered but not even the beginning or tendency towards them has been made manifest. We have particularly looked for evidence of sustained high frequencies; we are confident there are none.

Conclusions

1. Corona in the amount found upon arcing horns did not cause flashovers.
2. No voltage surges occur of sufficient magnitude to cause flashover or damage to apparatus.
3. Switching causes rises of voltage as great as any recorded.
4. Voltage rises recorded at the times of two flashovers may have been due to subsequent switching and were less than many known to arise from switching.
5. High-voltage switching as practised on this system may be done without fear of danger.
6. Only very occasionally did voltage surges travel even 35 miles without being greatly attenuated.
7. Such alternating surges as were found were highly damped, being usually of but one alternation.
8. There were no harmonic resonances or distortion of voltage wave shapes.
9. Residuals to ground were small.
10. There were no sustained high-frequency effects.

Acknowledgments

The author is pleased to acknowledge his indebtedness to Mr. W. W. Lewis of the General Electric Company for his kindly assistance and direction in the field in taking and interpreting wave shapes, and to Messrs. J. H. Cox and L. Gale Huggins for indefatigable work with the klydonographs and again to them and the Westinghouse Company for permission to borrow freely from their report, which has furnished the substance for a great portion of this paper. Mention must also be made of the unselfish consideration of Messrs. J. H. Cox and J. W. Legg who withheld a great deal from their own paper[3] so that this presentation of the search after the abnormal might be more comprehensive and complete in itself.

Discussion

Percy H. Thomas: This paper appears to clear away definitely the persistent suspicions that there is some source of mysterious overpotential inherent in 220-kv. or in very long lines that does not appear on the surface—something involving an unrecognized principle and jeopardizing reliability of service.

The subject of surges and high-voltage breakdowns has long been a *bête noir* for transmission operation. When power transmission first became of importance, one of the first serious sources of shut-down other than the ever-present lightning was the frequent short circuit of transformers in high-tension service. While this proved to be due partly to moisture and inadequate insulation, it was, nevertheless, necessary that the now well-known but then almost unknown effect of the steep-wave-front surge on windings be studied out[4] and this led to radical change in the method of insulating high-tension windings. While the theory of the propagation of surges or waves in transmission lines was academically known, nobody knew what the real effect in an actual line practically was, and this led to a certain feeling of uncertainty as to what might be expected with plant extensions. This led to a series of investigations in 1902 in the Middle West on a number of high-tension plants, similar in object to those reported by Mr. Wood and leading to a somewhat similar conclusion.[5] In the old investigation, the voltages were lower and the apparatus cruder, but the interest was much the same.

At a still later period, with the advent of larger systems and higher voltages, still another experimental study was made, this time based largely upon the oscillographs covering the action of switching and surges in the system of the Pacific Gas & Electric Company[6] and still again with the result of disproving the existence of any new or unexpected phenomena.

Mr. Wood's work goes over the research again, taking up all possible sources of excessive surges and using perfected apparatus. This makes clear the conclusion that the explanation of

3. loc. cit.

4. See paper, Percy H. Thomas, Trans. A. I. E. E., "Static Strains in High Tension Circuits and the Protection of Apparatus," Vol. XIX, 1902, p. 213.

6. Guiseppe Faccioli, *Electric Line Oscillations*, Trans. A. I. E. E., Vol. XXX, Part III, p. 1803.

mysterious surges even on 220-kv. lines must be sought among the well recognized laws of electric phenomena.

Considering, now, the detail of the paper, it may be pointed out that the results of the klydonograph appear to agree with the old fundamental rules of wave motion, e. g.: (a) When a potential is abruptly applied to a transmission line, a wave equal in crest to the applied potential passes along the line until it reaches a reflecting point when it is reflected back toward the start, reaching *double potential* at the *reflecting point,* neglecting losses, (b) When a small-capacity branch line leads from such a reflecting point, the wave starts off in the branch line at the maximum potential reached at the reflecting point and is subject to reflection at the end of the branch line with another doubling of the potential, (c) Whenever a condenser is charged through reactance (neglecting resistance) the potential will rise to double the charging potential and only gradually settle down to equilibrium after a series of oscillations.

As Mr. Wood properly says, in considering surges in a line, the effect of distance of travel is only to weaken the surge. Other things being equal, the effect of a switching operation is greatest nearby.

It is particularly gratifying to find that no abnormal *sustained* high-frequency potentials exist in the line, as these might be exceedingly troublesome.

F. W. Peek, Jr.: Mr. Wood's findings, which are quite in accord with theory, show no mysterious high voltages at sustained high frequency causing arcs of indeterminate distance. The expected highly damped switching surges occur but never of sufficient voltage to cause trouble. The cause of many arc-overs is dirt. In the tests made most of the dirt trouble was a purely mechanical one due to birds and as easily understandable as the effect of a fuse wire dropped over an insulator string. This investigation shows conclusively that there need be little fear from transient voltages originating in a grounded-neutral system.

Thus, in the part of the country where the lines of the Southern California Edison Company are located, the chief cause of insulator arc-over is a weakening of the insulators by dirt or other mechanical means.

Other important points brought out are that high-voltage switching may be done without fear, and that with quick-acting relays insulator arc-overs may be cleared without interruption of service. Of course, in addition to quick-acting relays, it is important to have grading shields or rings on the insulator to direct the arc away from the string while the relays are operating.

While dirt is the principal cause of arc-over in certain parts of the country, in other parts its effect may be practically negligible and lightning may be a very serious factor.

To illustrate how well Mr. Wood's conclusions are in agreement with our laboratory investigation I would draw your attention to a recent discussion of mine[7] at the Annual Convention which shows that our conclusions are very similar to Mr. Wood's.

C. L. Fortescue: Klydonograph is derived from two Greek words which mean wave and record. It is a device for making a record of surges. The klydonograph is a very simple instrument which consists merely of an electrode which is connected to the line through a potentiometer device, and measures a voltage proportionate to the tension of the line. This electrode passes over a sensitized plate or film in contact with the insulated surface of a grounded plate. Now the oscillation passing over the line makes a record on this sensitized plate which, after development, shows a figure possessed of certain peculiarities. A figure for a positive wave in any direction is different from the figure for a negative wave, so that it is possible to tell what the polarity of the wave is. One can tell whether it is an oscillating wave and, with certain arrangements, know not only the character of the wave, but also the steepness of the wave fronts and the direction in which the wave is traveling. So, with this device, it is possible to obtain very complete information about surges.

The method of determining the amplitude of the wave consists in measuring the diameter of the figure. The diameter is very closely proportional to the actual amplitude of the wave within the range in which this measurement is useful. In other words, for the higher voltages where the surges are of some concern, the calibration is very close, within 15 per cent.

The first klydonograph consisted merely of an ordinary sensitized photographic plate rotated under the electrode and the plate had dials which would register time on the record. The complete rotation occupied one day. This, of course, was not very convenient, inasmuch as the plates had to be changed every day. The present klydonograph is a much more suitable instrument. It consists of the same arrangement except that it has a roll film which goes over an insulated grounded cylinder. The roll needs to be changed only once a week and provision can be made for longer or shorter periods as desired.

Now, so far as possible, we are giving klydonograph service to those who have problems requiring investigation. We have about twenty of these seven-day instruments in operation. We have two experts whose work is devoted solely to looking after the instruments and giving this service. We have investigated quite a large number of systems in the east.

Of course, in carrying out this work we aim to do our field work as much as possible during the summer months when we have lightning, etc., so that we have been able to make only a preliminary analysis of the results. The preliminary analysis shows that in no case were there any signs of high frequency, and, in fact, the highest frequency we obtained was something less than 30,000 cycles per second. The duration of these surges is very brief. They don't travel very far. They very quickly become damped so the bogey of sustained high frequency does not exist. We haven't found it anywhere. Our experimental work has extended particularly over such portions of the United States in which lightning is very frequent and severe.

Lightning has proved to be the most prolific source of high voltages, but even lightning has caused nothing we need fear. The highest voltage hasn't gone beyond the possibility of insulation.

We expect to carry on this service to the best of our ability, but of course we are limited as to men and also as to number of instruments. On a large system it is pretty hard to do with less than a dozen instruments; to carry out investigations properly, one should have more.

We expect to do some theoretical work in the winter months, analyzing results of the investigations of the previous months; and we probably shall have to do some work on cable systems during the winter. Cable systems have been very free from surges and that, of course, from theory is what we expect. We wouldn't expect to have the surges in cables due to effects outside, and surges from cables connected to outside lines don't amount to anything at all. I don't think that the trouble with cables can be attributed to outside sources. The troubles with cables are inherently inside the cables themselves; surges may come about due to the trouble in the cables, possibly.

I may state that grounded-neutral systems have been very free from surges due to short circuits and other abnormal operations.

J. H. Cox: Mr. Wood's instructive paper leaves little to be said to lay the ghost of alarming abnormal conditions on the 220-kv. lines of the Southern California Edison Company. As pointed out, the tests were sufficiently extensive to be truly representative of conditions on those lines. Since Mr. Wood's paper tells the whole story so far as his system is concerned, it seems appropriate to present information gathered more recently with the klydonograph on other lines.

7. A. I. E. E. JOURNAL, October 1925, p. 1151

During the year 1925 surge investigations have been made on quite a number and variety of systems, both open-wire and cable. The causes of abnormal voltages on transmission lines may be classed under three headings, switching, short circuits and grounds, and lightning.

Switching. For the most part the experience with surges resulting from operating activity has been much the same as that on the Southern California lines. Switching surges in general are less than two times normal in terms of crest voltage to ground. Only two types of operations caused higher surges. One of these was the opening of an idle but energized line on a 15-mi., free-neutral line and caused surges as high as 4.3 times normal. The other was synchronizing with a high-voltage switch at the end of a 150-mi., free-neutral line. These surges reached a maximum of 4.6 times normal.

Short Circuits and Grounds. Experience with short circuits and grounds on other grounded-neutral systems has agreed with that on the Southern California Edison lines. No major surges on such lines have resulted from short circuits and grounds either accidentally or intentionally produced. Short circuits and grounds on free-neutral systems have, in general, produced high-voltage oscillations reaching a maximum of 4.5 times normal. These voltages were recorded on the two ungrounded phases in the case of a single-phase ground.

Lightning. As would be expected, lightning has thus far proven to be the best generator of high-voltage surges though in the California Edison System high voltages due to this cause were absent. No differentiation is made by this source between types of systems but it varies widely with locality. In one case a voltage of 1000 kv. to ground was recorded. Many other surges caused by lightning were recorded, ranging from 400 kv. to 700 kv. Some of these were oscillating and others unidirectional. The unidirectional surges were positive in polarity. The oscillating surges were usually recorded at times when an interruption was caused by the stroke.

R. W. Sorensen: During the past twelve years I have been much interested in these line flashovers. Some of our first theories as to the cause included mechanical means, such as spider webs, dirt, soiled insulators, etc. As a basis of the spider-web hypothesis there were found many big spider webs attached to the lines and it was supposed that these webs might become wet and cause some of the flashovers. The possibility of these flashovers being caused by birds was also considered. But, at that time, there was never sufficient conviction to warrant the expense of erecting devices to keep the birds away from the towers as has been done recently.

It is my endeavor in this discussion to encourage the idea of trying to solve our difficulties by doing simple things first, although it seems to be human nature to first apply complicated methods and later simple methods to problem solutions. One of the objects of engineering education should be to teach us, as engineers, to avoid a complicated method of attacking problems.

It must be borne in mind that, although it has not been mentioned in Mr. Wood's paper, he is dealing with a line to which are connected transformers with delta connections so that on this line there is no probability of getting effects such as arcing grounds might produce on Y-Y connections if these connections are not properly supplemented with tertiary windings connected in delta.

G. R. F. Nuttall: Perhaps it would not be out of place to mention the 220-kv. tie line between the Great Western Power Company and the San Joaquin Light & Power Company.

The design and tests on the standard towers have just been completed and Mr. J. A. Koontz of the Great Western Power Company has taken particular care to shield all points on the towers so that no corona will form near the wires. In order to reduce eccentricity in the joints, it is better to place the bracing in the cage of the towers alternately inside and outside. This inside bracing ordinarily offers quite a sharp edge which is a point where corona might form. Therefore we have bolted a small angle to the outside brace which exposes its flat side to the wire.

Mr. Wood mentioned that they used a dynamometer in stringing their cable. I wonder if we could have information as to the type used, as the spring type is unreliable at the higher tensions.

I should like to present for discussion the question of insulation, not of the line itself but at the ends of the line. Mr. Wood's paper has given us useful information on transient voltages and 220-kv. operation and I wonder what the manufacturers' views are as to the rating of their bushings for oil switches and transformers.

In the case of the Pacific Gas & Electric Company and the Southern California Edison Company, I think I am right in saying that the A. I. E. E. ruling (Sept. 1922) has not been upheld. The switch bushing ought to be tested for 2¼ times the line-to-line potential which equals 495 kv. for 220 kv. operation, and the transformers (three single-phase, auto-transformers with grounded neutral) at an induced voltage of twice line-to-line potential plus 1000 which equals 481 kv. for 240 kv. at the sending end.

L. N. Robinson: In connection with Mr. Wood's paper, the most effective cure for the flashovers seems to be the bird guards. I wish Mr. Wood would give us a description of them.

D. I. Cone: I wish to comment on a by-product result of Mr. Wood's paper. The table on the seventh page and the oscillograms tells of the investigation of the normal residual currents of the system which were found to be without features that would aid in the explanation of transients. This record, if supplemented by data regarding the sizes of transformers, their characteristics and connections, will be of considerable value to the Joint Committee of the National Electric Light Association and the Bell Telephone System, which is studying the distribution of such residual currents in systems of this kind. A special project committee is doing work with a view to enabling us to predict these residuals and their resulting inductive effects upon neighboring lines.

Roy Wilkins: In the discussion on Mr. Wood's paper the question is brought up regarding the insulation on the oil switches and bushings and transformers used on the 220-kv. line. The transformers and switches themselves are tested for 2.73 times the normal voltages to ground, the bushings at 2.25 times line voltage. There is before the Institute's Standards Committee at the present time the proposition to change the requirements for the potential tests on grounded transformer equipment to some such value at 2.73 times line voltage.

H. Richter (communicated after adjournment): The paper states that, on the small overhead networks, the transformers are of the type having a network protector in the same case. This form of network protection has been abandoned on the two systems where it originated, because of faulty operation and lack of real protection. Experience shows that these devices are excellent transformer protectors but cannot be relied upon for network,—that is, service protection. I am rather inclined to ascribe the excellent record of 0.7 per cent transformer burn outs mentioned on the seventh page to the lightning protection offered by the common system neutral, as emphasized on the fifth page. As these protectors are so designed that they do not protect against trouble in the primary or secondary lines, their cost of about $3 per transformer-kv-a. makes a rather high insurance rate against transformer trouble. The substitution of carbon circuit breakers tripped by reverse-power relays in the underground area of Minneapolis is in line with the latest methods of network protection where real reliability of service is demanded.

In general it may be said that the loop method of primary

feed is particularly applicable to bulk loads of 300 kv-a. up and fed at the higher primary voltages of 11,000 volts and above. This is because of the high cost of spare capacity in feeders and substation apparatus, high rupture capacity, loop-sectionalizing switches, and pilot-wire control. For underground areas where transformer banks, serving miscellaneous distribution loads, range from 75 to 300 kv-a. each and are spaced on the average 500 ft. apart (but may be up to a maximum of about 1000 ft. apart) there is being installed in six large cities and planned for many others a very simple system of a-c. distribution. This is the secondary-network system with automatic network protection that was described by A. H. Kehoe[5] and by W. R. Bullard,[6] and that has been in successful operation in New York City for almost three and a half years.

In this network system the feeders are radial, no primary protective or sectionalizing devices being necessary. The secondary mains are spliced together to form a solid mesh which requires no junction boxes, and a compact triple-pole network unit inserted in the transformer-secondary connections to the network protects for every type of fault that might interfere with continuity of service except failure of the prime source of power. Advantage is taken of the elimination of primary switches, cut-outs, and disconnecting potheads, to employ higher primary voltages such as 13,200 volts. Thus may be saved the cost of either station step-down transformers and lower voltage switches, or even of the entire substation. By limiting the feeder capacity to 150 amperes, each feeder can carry about 3000 kv-a. and be confined to either a small or a large area depending on the load density.

The system of multiple street lighting introduced in Minneapolis is undoubtedly a step ahead both from an operating and economic point of view. However, some electric service companies object to pilot wires for control and others to mercury switches. One manufacturing company has developed a system of control by a form of carrier current over the primary feeders. This dispenses with both of these features and also the reenergizing contactors. The switching units are sturdy, comparatively simple, will not be expensive, and are small enough to mount in the vase of an ornamental post. They can also be used in conjunction with a primary switch for controlling pole-mounting constant-current transformers feeding series lamps. The sender at the station is likewise simple and substantial. Further, there are practically no losses in the switching units.

The system has had a successful trial equivalent to a year's service. It is anticipated that this method of control, together with multiple street lighting, will be the standard street-lighting system of the future.

R. J. C. Wood: There was a question asked about possible slipping of aluminum on steel with changes of temperature. I have given that matter quite a little thought and have come to the conclusion that there is no longitudinal motion between the two metals. Imagine a piece of cable, steel inside and aluminum outside; somewhere it has two ends clamped together, so that the two ends cannot move with respect to each other. If you make it sufficiently hot the aluminum expands away from the steel, but in an actual line, the tension of the cable is sufficient to stretch the steel so that the aluminum does not become loose. In actual construction, I doubt if you will find separation of the aluminum from steel. They will act together as a unit with this exception: with changes of temperature the stress passes from one to the other. The hotter the metal, the greater the stress in the steel; the colder the metal, the more stress in the aluminum.

In closing my paper: the design of the bird guards has been a matter of trial and error. We equipped a portion of the line with what is known as Mr. Barre's bird pans. The bird pans consist of a horizontal tray of metal lying on the lower member of the top crossarm, the idea being that it would form an efficient mechanical shield between the bird and the conductor. Apparently they have worked quite successfully, the only objection being that they are rather expensive, and unless they are very well anchored to the members of the tower, the ordinary vibration sets them imitating big drums, so that there has been some complaint from real estate agents trying to sell property in the immediate neighborhood.

There is another kind of bird guard which is simply an exaggerated saw-toothed, galvanized iron, the points being perhaps 1½ or 2 in. apart and with a height of some 6 in. so that it is a very acute point which is not comfortable to the bird. These were fastened along the members of the tower for a distance of approximately 5 ft. on each side of the center conductor. This line, by the way, is of horizontal construction, and similar pieces of metal were fastened to the sloping portion of the crossarm in the outer positions.

When we first put up these bird guards as mentioned in the paper, we didn't know what a clever fellow the bird was, and we put up one kind of a guard to protect the place we thought he was going to roost upon, but, driven out of there, he took the next best thing. He even went so far as to climb into a little piece of 6-in. channel which is underneath the main crossarm, a piece only about a foot long, which is a part of the structure from which the center string of insulators is hung. When prevented from getting on the main body of the crossarm, he flew underneath and got into this little cage place, so we have had to protect that too.

Regarding the residual currents and the situation of the transformers and auto-transformers, the information Mr. Cone asked for can be given him, but it really will not be of very much use since it refers to a line which is not transposed. We have been trying ever since the line was built to find time to transpose the conductors, but we have never had time to take the line out of service and do this work. As soon as the third line is in, we expect to be able to take out the other two lines, one at a time, and transpose them. This will balance them, statically, against ground, and will reduce to a considerable degree that residual current.

Fundamental Considerations of Power Limits of Transmission Systems

BY R. E. DOHERTY[1]
Associate, A. I. E. E.

H. H. DEWEY[1]
Associate, A. I. E. E.

Synopsis—At this time the power limit of transmission lines is a live subject and presents such complications as to require very careful analysis. The paper points out the essential features to be considered in a study of the problem, and calls attention to some outstanding results of an experimental investigation of the subject with a view to clarifying some of the points that have been under discussion in the past two years.

It is shown that the problem of stability is not necessarily confined to long-distance, high-voltage transmission, but may be present in any system where the impedance of the transmitting circuit is high compared with the load to be carried.

While the impedance of the transmission line and transformers plays an important part in establishing the breakdown point of a system, the characteristics of synchronous apparatus with the method of voltage regulation used are of equal importance.

It is shown that the synchronizing power of synchronous apparatus is largely dependent upon the field excitation at the time excess load is applied, that field excitation is determined by the circuit conditions under steady load, and, in order to provide for increase of excitation with increasing loads of considerable magnitude, some automatic means of controlling the field is essential.

The rate at which mechanical load in large quantities can be added to a system is limited on account of the necessity of change in angular displacement between the generators and receiving bus; this changing angle requires relative speed change, which takes time. This fact, together with the inherent tendency of synchronous machines to "stiffen" under sudden applications of load, makes it possible to rely on the usual vibrating-type voltage regulator working on the field of the exciter to provide the necessary field change. It is brought out that the maximum load that a system can carry under steady conditions at normal voltage can be suddenly thrown on, and the voltage regulator, with the assistance of the factors mentioned, will provide the necessary excitation.

Voltage regulators are practically a necessity where it is desired to approach, under operating conditions, the ultimate maximum power of the system.

Transient load changes that occur on the usual system, such as throwing on or off load, cutting in or out transmission circuits, etc., can be easily taken care of, providing such changes do not exceed the steady state limits of the system.

The effect of short circuits depends upon their nature, whether three-phase or single-phase, and upon the location and duration. This subject is discussed briefly and the conclusion drawn that successful operation can be obtained under usual short-circuit conditions if adequate relaying is provided.

The possibility of increasing the limit of power transmission by improving the apparatus and the characteristics of the transmission circuits is discussed, and it is pointed out that no great development may be expected from any scheme yet proposed regarding a modification in line characteristics. With reference to the apparatus, it is possible to make some changes in the design of synchronous machines tending to "stiffen" them, such as higher saturation, larger air-gap, etc., but in general no radical improvement may be expected here that does not materially increase the cost and decrease the efficiency of the machine. Attention is turned therefore toward such schemes of regulation, or compensation, of the synchronous apparatus as would increase the maximum power. Among these is the use of reactors for locally controlling power factor and thus too the field excitation of the more important synchronous machines. However, the possible additional power thus obtained is limited, and, as it now appears, other methods which have greater promise will be resorted to.

The use of a mercury-arc rectifier in the alternator field circuit seems to have great possibilities. By varying the field current in rigid proportion to the armature current, a very significant degree of compensation of the armature reaction is obtained—about 50 per cent, which is, of course, equivalent to almost doubling the inherent capacity of the generator. While this scheme is not yet in practical form, its efficacy has nevertheless been demonstrated in factory tests, and it is regarded by the authors as one of the most promising developments at this time.

* * * * * *

THE problem of power limits of transmission systems has within the last few years assumed importance in the study of long distance transmission of large blocks of power. Fundamentally there are no new elements entering into the use of long lines operating at high voltage that would be disturbing were it not for the fact that economic considerations require an approach closer to the maximum power which it is possible to transmit than has been the case in most of our existing systems.

In general, the problem is not confined to long distance transmission, but is one that may be met at any time where the impedance of the circuit from the scource of power to the point of consumption is comparatively high. There have been a number of isolated cases cited wherein the limit of stability has been reached and synchronous systems have pulled apart, where no great distance of transmission was involved. The growth of power networks is now so rapid, with interconnections that will require transfer of such large amounts of power, that it is essential that the principles on which stability of operation depends be thoroughly understood.

The rapidly increasing demand for electric power requires extensive development of our national resources with consequent growth of long distance transmission. The economical use of our water power, as well as mine mouth steam plants, makes it necessary to keep the investment in transmission lines as low as possible, which involves carrying the maximum amount of power feasible over each line with due regard given to continuity of service. Matters of efficiency and regulation can be met by well-known methods and the question of the maximum amount of power that can be transmitted over a single circuit becomes one of stability

1. Both of General Electric Co., Schenectady, N. Y.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

of the line with its connected apparatus. It is necessary, therefore, that all the factors entering into the problem be thoroughly well known and appreciated, as errors may be extremely costly both in investment charges and quality of service.

While great stress has rightly been laid on the limiting effects of long lines as a determining factor in stability, it is nevertheless true that no general conclusion can be drawn as to the probable limit of power from data regarding the line alone. There are many other elements that assume varying importance with different lengths of lines, such as different characteristics of generating and receiving apparatus, different types of regulating devices, etc.

The papers[2] that have been read and the discussions that have taken place on this subject during the past few years have shown such varied viewpoints that one who has not made a special study of the subject may easily be confused as to what the real problem is and its practical importance to the industry.

It is the purpose of the authors to outline the underlying considerations of the problem, with particular reference to the factors which determine power limits under various operating conditions, and to cite a few of the more significant results of an extended investigation. The details, both of the methods of analysis and of the calculated and test results, will be presented in forthcoming papers. In other words, the present paper is, to a great extent, merely a statement of the problem, a discussion of the factors involved, and an indication of the direction in which the investigation is leading.

Most of the studies of stability of transmission systems that have been made have been on lines of from 300 to 500 miles in length designed to operate at 220 kv. This fact has led, in some cases, to the erroneous impression that there is something inherent in the use of 220,000 volts for transmission purposes that may limit the amount of power which may be transmitted with stability. It should be borne in mind, however, that there is a definite limit of power which may be transmitted over any system regardless of voltage or length of line and it is just as possible to encounter unstable conditions in a line one mile long, operating at low voltage, as it is to encounter it in a long line at high voltage. It is merely a question of how close to the power limit normal operation may bring us.

With a given installation of synchronous apparatus, the amount of power that can be transmitted over a connecting circuit is, generally speaking, decreased by increased impedance and vice versa. With the growth in capacity of some of our large steam generating systems, requiring extensive use of power limiting reactors, it is necessary to take the matter of stability into account and avoid the possibility of too much reactance between large generating stations or even sections of the same station. There are a few well-known cases on record where the power limit has been reached between stations and loss of synchronism with consequent shutdown has resulted. This has occurred in systems operating at all voltages and varying lengths of connecting lines.

The stability problem, then, is not an entirely new one, though cases of trouble from this source have been sufficiently isolated and of such a special nature as to cause little stir among operating engineers.

On extremely long high-voltage lines there is another factor in addition to high impedance that has a tendency to limit the power to be transmitted with a given synchronous installation. The charging current of such lines becomes quite an item and, contrary to that which might be expected, may reduce the maximum power. This is brought about from the fact that, although the charging current reduces the effective impedance of the line, it also lowers the necessary excitation on the synchronous apparatus by reason of the higher power factor. This feature will be discussed later in greater detail. It is practically the only factor in long high-voltage lines tending to affect stability that may not be present in short low-voltage lines.

The matter of charging current may also become important in underground transmission, especially if the voltage of cables is raised materially. While this problem is not before us just now, the tendency toward higher voltage underground may place it there in the future.

An analysis of the problem of the determination of the limit of power on a given system involves a close study of not only the characteristics of the transmission line, transformers, generators, exciters, synchronous condenser and receiving load, but the method of operation and system of regulation as well.

The phenomenon of breakdown of a synchronous motor operated from a bus of large capacity is pretty well known. If the shaft load of such a motor is gradually increased it will finally reach a point at which no more electrical power can be supplied to the motor, even though the bus voltage remains constant, and the motor will drop out of step. The amount of electrical power which can be supplied to the motor at a given voltage depends upon its internal impedance and its excitation at the time the load is applied. If the excitation remains constant at its no-load value, breakdown will occur at a much lower load than if the excitation is increased.

A synchronous generator functions in a manner similar to a synchronous motor and can be driven out of step with the bus, if a prime mover of sufficient capacity is connected to it. The amount of shaft power necessary to drive the generator out of step with the bus depends upon its internal impedance and the excitation at the time.

If a synchronous generator is used to furnish power to a synchronous motor of the same size and characteristics, and with excitation on each machine correspond-

2. Groups of Papers presented at A. I. E. E. Convention at Philadelphia, Feb. 1924, and New York, Feb. 1925.

ing to no-load normal voltage, then when the shaft of the synchronous motor is loaded, both will drop out of step at a value of load that is approximately one-half of that which either would carry if connected to a bus of the same voltage and of infinite capacity. This is due to the fact that their impedances are in series and of twice the value of a single machine. As the motor is gradually loaded, it drops back in phase position with respect to the generator and drops out of step at a definite angle.

Going a step further, if a synchronous generator is used to supply power to a synchronous motor through a reactor or over a transmission line, there will likewise be

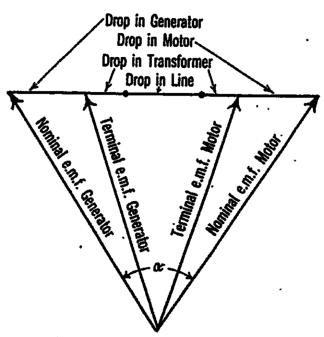

FIG. 1—SYSTEM VOLTAGE VECTORS

a definite breakdown point which, at a given excitation on each machine, will be less than before the reactor or transmission line was inserted. This is, of course, obvious, as the line or reactor causes in itself an added impedance drop and an added angular displacement between the generator and synchronous motor. In other words, the power first appears in electrical form at the generator, then successively passes through intermediary apparatus including transformers and line and finally through the motor. That is, it passes through a succession of electric circuits in each one of which, including the generator and motor, the power flow causes an impedance drop. This changes the magnitude and displaces the phase of the voltage as shown in Fig. 1. In the simple case considered, the components of impedance drop add in series, producing a total displacement between the internal, or nominal, voltage[3] of the generator and the internal voltage of the motor. The maximum power in this case is proportional to the product of these two voltages, *i. e.*, the field excitations, inversely as the total impedance between them, and occurs when they are displaced by a definite angle which is usually less than 90 deg.

The matter of excitation as noted above is thus one of the greatest importance in the problems of maximum power limit. Indeed, on short lines the difference between the breakdown point with no-load normal voltage excitation and with full load 0.8 power factor excitation may be as much as 100 per cent.

3. Corresponds to the value of field excitation.

At first glance, it may seem a simple matter to provide sufficient excitation to obtain high synchronizing force in the synchronous apparatus, but it is really a rather complicated problem. The excitation for any given voltage at the terminals of an alternator depends upon the power factor of the load. As mentioned above, in the case of the alternator driving a synchronous motor of equal size, there is no leeway at all in the control of the total field excitation of the two machines, if the terminal voltage is held constant. A reduction in the field excitation of the synchronous motor will require an equal addition in the field of the alternator and while one is weakened the other is strengthened a similar amount and no gain results.

In the case of long-distance transmission lines it is desirable, so far as the line is concerned, in order to keep the losses and regulation of the line at a reasonable figure, to deliver power at the receiving end at a high power factor. This results, however, in a high power factor on the generators at any given load and consequent lessening of their breakdown capacity. As a matter of fact, some local low power factor load on the bus at the generating end of a long-distance transmission system may actually increase the maximum power possible over the line by increasing the generator excitation.

In this connection it will be noted that a high power factor load is actually a detriment in so far as it affects synchronizing power, and it is certainly one of the

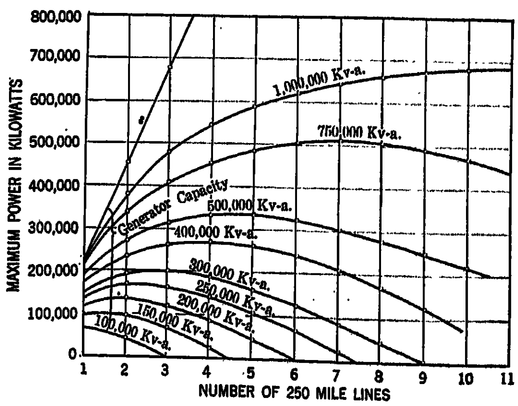

FIG. 2—MAXIMUM POWER WHICH CAN BE TRANSMITTED OVER A STRAIGHT-AWAY 250-MILE LINE AT 220,000 VOLTS, SHOWN AS A FUNCTION OF THE CAPACITY OF SYNCHRONOUS APPARATUS, AND THE NUMBER OF TRANSMISSION CIRCUITS. SYNCHRONOUS MOTOR LOAD ASSUMED.

phenomena that should be taken into account in the design of a long distance transmission system. It may come as somewhat of a shock to many engineers who have not made a close study of this problem, to learn that the inherent charging current of a long high-voltage line actually reduces the maximum power that can be transmitted with respect to that which could be carried over a line of similar reactance without charging current. The authors have made actual studies showing that more power could be carried over two high-voltage long-distance lines in parallel than over three with a given

installed generating capacity. This is merely an illustration of the effect of reducing the excitation on the generators by the excess charging current of the third line in a case where the impedance of the generators is an important factor.

Fig. 2 will serve to illustrate this point. It will be noted that for the 250-mile, 220-kv. line considered, there is a definite relation between the installed synchronous capacity and the number of transmission circuits that will give maximum power over the system. In the case of 300,000-kv-a. synchronous capacity of usual design at each end of the line, three circuits will carry approximately 200,000 kw., while five circuits will carry only 160,000 kw. and nine circuits, no power whatever. This effect would be still more pronounced in the case of a 500-mile line.

It has been suggested that the bus at the generating station end of the line be loaded with reactors to allow the transmission line a high power factor load but to lower the power factor on the generators themselves. This would increase the excitation and thus the maximum power that could be taken from the system. This plan shows some real possibilities and under certain circumstances may be employed, although there are other methods of obtaining similar results that may be used to better advantage.

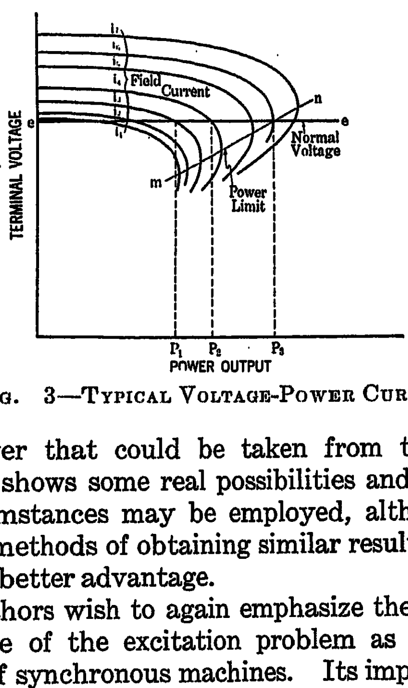

FIG. 3—TYPICAL VOLTAGE-POWER CURVES

The authors wish to again emphasize the very great importance of the excitation problem as a factor in stability of synchronous machines. Its importance has been recognized before by the authors of previous papers on this subject, but it has not been given quite the prominence that we feel it deserves. Were it possible to absolutely control the field current of synchronous machines as desired, the problem of stability would be very much simplified.

With the importance of field excitation in mind and the knowledge that under fixed conditions of load, voltage, and power factor, the strength of the field will also be fixed, it will be seen by reference to Fig. 3 that only a small increment of load may be added without breakdown unless the field excitation is changed. For instance at power p_1, corresponding to field current i_3, and normal voltage e, it would be possible to increase the load about twenty per cent, or if operating at power p_2, excitation i_4, the possible increase would be only six per cent. If means are provided, however, to automatically increase the excitation as load increases, the maximum power could be increased to p_3, which is the ultimate maximum that could be transmitted at normal voltage. This maximum could be reached regardless of what load was being carried at the time the increased load came on.

The authors of some of the early papers laid considerable stress on the point that voltage regulators in general use, while tending to follow the load requirements by increasing the field current as needed, were entirely too slow to do so adequately when the time transient of the exciter was taken into account. The argument looked entirely reasonable when it was suggested that increased load might be thrown on instantly, as by dropping off a large turbine generator at the receiving end—thus dropping its load on the transmission line. Fortunately there are compensating features in the characteristics of the system, and the linkage between the armature and field of the alternator make it possible for the ordinary vibrating type of voltage regulator and a properly designed exciter to supply the needed excitation at any rate at which load can come on to the line and generating station.

The explanation of this phenomenon which the authors feel is of the greatest moment lies in two important facts: first, that large blocks of system load cannot be thrown on the generators instantly, as the angle between the generators and receiving apparatus must increase—this requires a slowing down of the receiving system which, of course, takes time—and second, as load comes on the generators, the sudden increase in armature current induces a field current tending to hold them in step. These two phenomena consume sufficient time to allow voltage regulators and exciters to function, furnishing the necessary field current to maintain voltage at the greater load. A more detailed discussion of this point will be given later on.

This point brings out the very great importance of the use of voltage regulators in a long distance transmission system, as the maximum load safe to carry over a line, from the standpoint of stability, will be increased in some cases more than fifty per cent by their use. This important consideration, in the authors' opinion, has had practical demonstration in some existing systems that have operated for some years without difficulty from lack of stability. Many cases that have come to our attention would be on the ragged edge, if not impossible to operate, without voltage regulators.

The foregoing discussion covers, in a general way, the simple case of a generating station feeding a synchronous load approximately equal in kv-a. capacity. For such a case the maximum power is easily calculable and there are no serious problems when the matter of excitation and regulation are understood and properly provided for.

When complications arise, such as the generating

station feeding more than one independent transmission line or when the receiving end is a network with generating capacity and load of its own, the problem becomes difficult. In general, the more synchronous apparatus there is connected to either the generating or receiving-end bus, the more nearly will the maximum power limit of the line itself be approached, because the condition of infinite buses is being approached. Generating stations tapped into the middle of a long line, or synchronous condensers of large capacity used either at the receiving end or in the middle of the line, increase the maximum power that can be transmitted over a given system. The calculation of the actual power limits in such cases becomes very complicated.

During the past year the authors, in conjunction with other interested engineers, have been carrying on an extensive series of tests in the General Electric Company factory on an artificial transmission system equipped with synchronous generating and receiving apparatus, synchronous condensers, voltage regulators, transmission lines, adjustable as to the length, characteristics, etc. With this equipment it has been possible to set up almost any combination of conditions that might obtain in a practical installation and to vary the characteristics of individual pieces of apparatus in any way that might show promise of interesting results.

The experimental work on this artificial system has been paralleled by mathematical analysis throughout and not only has a mass of valuable data been obtained showing the effect of modifications in design or operation of the equipment under varying conditions, but methods have been developed which the writers feel will be of great assistance in the solution of any practical problem. The results of this comprehensive investigation, which is now being completed, will be published in the near future.

In the foregoing, the larger aspects of the problems which have arisen in connection with the development of power transmission in this country have been discussed in a general way, and the situation has been outlined as it exists today with respect to the use of standard apparatus. In that which follows, the problem of possible future increase in power limits will be stated and analyzed in terms of the various factors which determine the present limits, and possible solutions will be suggested.

Influence of Synchronous Machines

As already suggested, in those problems in which stability is a practical factor, the outstanding fact is the usually predominating influence of the impedance of the synchronous apparatus. For illustration, consider a 500-mile straight-away transmission line at 220,000 volts. If there were no power limitations in the electrical apparatus at the ends of the line (the conditions usually referred to as "infinite bus"), the power limit of the system, *i. e.*, of the line itself, would then be about 130,000 kw. With synchronous apparatus of the usual design and of the usual capacity with respect to the power to be transmitted, the limit becomes about 70,000 kw., or practically half. This point may be further emphasized by the fact that a few actual proposals have been studied in which the line, less than a hundred miles long, was practically a negligible factor. Hence the power limit is imposed in such cases largely by the impedance of the synchronous machines.

When this fact was first encountered, a number of plans for increasing the maximum power of the system were suggested, but much of the promise of success disappeared upon analysis. Larger generators might be used, but that was too costly. Another line might be added, but that was not only costly but, in the long lines, it actually decreased instead of increased the maximum power. Studies have been made of the use of series static condensers in the line of sufficient size to neutralize, at least partially, the reactance of the line and transformers. Theoretically, there are great possibilities in this scheme, as the total reactance of a line of any length can be reduced to a negligible value. The present high cost of condensers, together with certain difficulties of operation, render this plan out of the question for the present but it is one worthy of further attention for engineers studying this subject. A scheme[4] was proposed for decreasing the reactance and increasing the capacitance of the line, but although this might improve the line regulation, it did not gain favor, partly on account of the difficulty of construction, but principally because it would further weaken the generators by increasing the charging current. An exciter which would respond very quickly to the voltage regulator might, it seemed, strengthen the generators and thus increase the ultimate maximum power at normal voltage, *i. e.*, greater than p_3 (Fig. 3); but it was early recognized that this could not be accomplished by such an exciter and vibrating type regulator. Such regulation makes it possible, as already mentioned, to carry the ultimate maximum, corresponding to p_3 in Fig. 3, even if this is thrown on the system suddenly—but not significantly more than that. Thus, when all of the above proposals have been analyzed, the situation is not far different from the starting point with respect to increasing the ultimate maximum power under steady operation at normal voltage.

Yet this is what must be done, if it is hoped to transmit power over long lines—500 miles or more—in synchronous operation. There may be some other and better way to do it than in synchronous operation, but, if the latter is to be retained, the problem of increasing the maximum power reduces to one of stiffening up the synchronous apparatus.

Thus, the problem to which a number of interested engineers have been directing their attention has been along two general lines. One has been to "stiffen" the

4. "Output and Regulation of Long Distance Lines," Percy Thomas, A. I. E. E. Trans., Vol. XXVIII, p. 615, 1909.

synchronous apparatus, and thus approach the power limit of the line itself. The other, perhaps looking considerably to the future, has been toward finding some other means than synchronous operation. Regarding the latter, however, there is little of interest, to the authors' knowledge, other than that such studies are being made. In the light of the past growth and the probable future, such limits as that even of the line alone, cannot, of course, be accepted as final. Hence the situation demands such studies. However, the hope of the immediate future lies in the other direction —in finding such modifications and auxiliaries in connection with present synchronous apparatus, including the synchronous condensers, as will make possible a nearer approach to the power limit of the line alone.

The problem of stiffening the synchronous apparatus has been attacked along two general lines. One relates to schemes of regulation of the more important synchronous machines, the other, to modifications in design, which, in effect, would result in machines of higher *inherent* power capacity—that is, lower reactance. The former include the regulation of the field current, the use of shunt inductances across the generator terminals, and any other schemes which would apply to regulating currents from an exterior source. On the other hand, to lower the reactance of the machine itself is, of course, a problem in the design.

Conditions of Operation

Before taking up in detail the questions of design and regulation, it is well to consider the conditions of operation which affect the problem of maximum power. The study of this problem resolves logically into the consideration of two conditions of operation. In one, technically referred to as *steady state*, all forces involved in the entire system are in stable equilibrium. The power flow is everywhere steady, and in the apparatus the voltages, field excitation, magnetic flux, etc., are all constant. Everything is balanced and steady.

In the other, referred to as *transient state*, conditions are changing. Power flow, speed, magnetic flux, voltage—all of these are in a state of change.

Now the maximum power which can be transmitted, and, to a limited extent, the amount which it is necessary to transmit, depend upon the state. If, during steady state operation, a load is suddenly thrown on, or a loaded generator is dropped, or a short circuit occurs, a readjustment or transient must follow in speed, power, voltage, magnetic flux, etc., before steady conditions are again established. During this change, the synchronous apparatus all becomes inherently more powerful, or "stiffer," than in steady state, as explained under *transients*, but, due to possible "overshoot" of power on the swing of load following the shock, the power which must be transmitted may also be increased above that required after the system settles down. If a weight attached to a spring is suddenly dropped, thus stretching the spring, it will drop, on the first swing, not to the steady state position where the spring tension equals the pull of gravity, but will overshoot, throwing additional tension on the spring. If we imagine the stiffness of the spring to increase temporarily during this transient state, the analogy with the present problem would be fairly complete. The maximum power which can be carried is temporarily increased, but the amount which it is necessary to carry is also increased.

Steady State

The steady state operating characteristics of a generator supplying power to a transmission system are shown on Fig. 3. It will be noted that as the field current, shown as parameter, is increased, the maximum power—*i. e.*, the limit of stability, where the slope of the voltage-power curves is infinite—is progressively greater, and occurs at successively higher voltage as indicated by the line $m\, m$. Hence there is a particular value of field current, i_6, for which the maximum power occurs at normal voltage. This is obviously the ultimate maximum which the system can carry at normal voltage. While a still greater field current i_7 would give greater maximum power, it would nevertheless occur at a voltage higher than normal.

Influence of Field Excitation

In Fig. 3 it will be noted that operating at power p_1 and at normal voltage e requires a field current i_3. If the power were increased to p_2 without changing i_3, the system would break out of synchronism, since the maximum power with i_3 is less than p_2. Thus, when any system is operating as near the limit as in the above illustration, the field current must be promptly increased as the load is increased, to hold the voltage along the line $e\, e$. The question of the rate at which load can be applied, as well as other transient conditions, will be discussed later. The point to be observed here is that the degree of stability is indicated by the slope of the voltage-power curve; that the maximum power is greater, the greater the field current, and occurs at an ever higher terminal voltage; and that there is therefore one field current i_6 for which the maximum power occurs at normal voltage. And this is the ultimate maximum which can be transmitted under steady state at normal voltage.

It may be further stated as a very important fact bearing on the characteristics of synchronous generators that, roughly, the greater the field current *at the same voltage*, the greater the stability and maximum power, regardless of what means are used to obtain the larger field current. Thus, to lengthen the air-gap of the machine or increase the degree of magnetic saturation, or decrease the power factor of the load by connecting across the terminals a shunt inductance—any of such measures will require more field current at the same load and voltage, and therefore improve the stability and maximum power.

The steady state characteristics of synchronous condensers are, of course, very similar. These comprise a set of curves of the same general form as those in Fig. 3

and involve the same quantities, except that the abscissas are reactive kv-a. instead of active power. Similarly, the maximum value of reactive kv-a. which the synchronous condenser can deliver is progressively higher and occurs at successively higher voltage, as the field current is increased.

Parallel Operation

In both of the above cases, the characteristics are for a single machine. Suppose, for instance, that three or more generators, instead of one, are connected to the bus. Then what are the characteristics? If the units are all alike, including the governor characteristics of the prime movers, and the excitation currents of all units are kept equal, then a similar set of characteristics as in Fig. 3 could be drawn, taking field current as parameter. These would represent the voltage-power characteristics of the bus. In the successive steady state conditions after increments of load are added, the governors have placed correspondingly more power, the regulators correspondingly more field current, on all machines. So they all reach their respective power maximum at the same value.

However, if the units are different, additional parameters are necessary—the governor characteristics and settings for all prime movers, and also the distribution of field current on the several generators. Under this condition, the units do not reach their respective maxima at the same total load. Thus, when there are a number of units in parallel, the steady state limit of the combination is a function of the distribution of load and of field excitation, and also of the governor characteristics. And there is an optimum distribution which gives the greatest power, and this is such that all reach their respective maxima at the same total load.

The same is true of a number of branches of a power network connected to the same bus. Each branch may be from a power bus such as just discussed, involving the parameters mentioned. So while the problem of the extended combination is, of course, still definite, it is nevertheless greatly complicated by additional parameters.

So, in general, systems under steady state operation can be characterized by such curves as shown in Fig. 3. As generators are added, the slope of the curves becomes less, reaching zero with an infinite generator capacity. Up to three or four branches the characteristics are amenable to reasonably definite calculation. Beyond that, resort must be made to simplifying approximations or equivalent circuit tests. Methods of calculating the simpler cases of steady state conditions have been published[5]. Extensions and additional methods will be presented in the near future.

Transients

In transient conditions, many factors, in addition to those which influence steady state operation, are brought into play. Among these are the momentum of rotating masses, and the time element in both the electromagnetic circuits and in the governors.

Sudden Application of Load. In Fig. 4, if load is suddenly thrown on the shaft of the motor, the electrical power to the motor can not increase until the motor drops back in phase, which requires a temporary drop

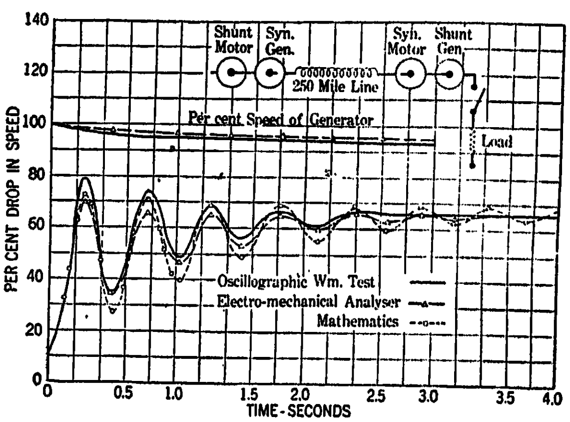

Fig. 4—Transient Conditions Following a Sudden Application of Load

in speed. This means that the initial increased demand was partially supplied from the momentum of the motor, causing the electrical power supply to increase more gradually, thus lessening the shock to the system. Moreover, the load which first falls on the generators is initially supplied from the momentum of the rotors, until the speed drops, after some oscillation, to that value at which there is balance, determined by the governor, between mechanical input and electrical output. Fig. 4 shows the transients for an analogous case as indicated.

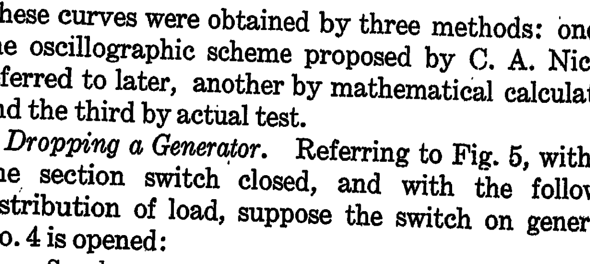

Fig. 5

These curves were obtained by three methods: one by the oscillographic scheme proposed by C. A. Nickle[6], referred to later, another by mathematical calculation, and the third by actual test.

Dropping a Generator. Referring to Fig. 5, with the line section switch closed, and with the following distribution of load, suppose the switch on generator No. 4 is opened:

Synchronous motor No. 3	400,000 Kw.
Generator No. 1	100,000 "
Generator No. 2	280,000 "
Generator No. 4	200,000 "

5. Group of papers and discussion by Edith Clarke and C. A. Nickle on this subject presented at the Midwinter A. I. E. E. Convention, Feb. 1924.

6. "Oscillographic Solution of Electromechanical Systems", by C. A. Nickle, A. I. E. E. Convention, Saratoga Springs, June 22-26, 1925.

Fig. 6 shows the nature of the resulting transients.

At first, the power flow and the electromagnetic torque of the various units are quite independent of the torque on the shaft of either the motor or generators which is determined completely by the electrical constants of the system, since due to the inertia of the rotating masses, the relative-phase positions of the rotors remain, for the moment, what they were before the switch was opened. After a transient, the system settles down to power conditions as determined completely by the governor on the prime movers. Thus, in the first moment the power flow is determined by the constants of the electrical circuits, and in the last, by the governors.

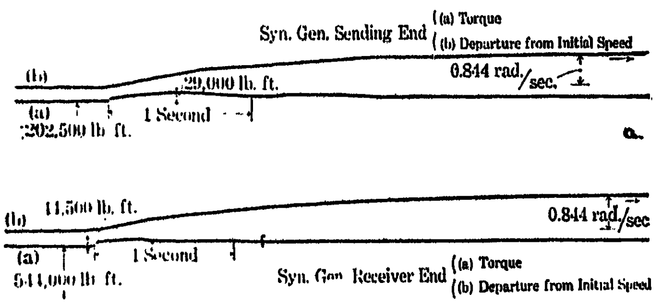

FIG. 6—TRANSIENTS DUE TO DROPPING GENERATOR NO. 4 FROM SYSTEM IN FIG. 5

Switching out a Section of Line. Another case is that in which a section of line is suddenly opened, as indicated in Fig. 5. The load distribution is the same as above, except that Generator No. 4 is disconnected. This sudden interposition of added reactance requires a phase adjustment which does not increase the steady state load on the system, but it does cause a power oscillation which usually overshoots the steady state value. This contains all of the transient elements discussed above, and is illustrated in Fig. 7.

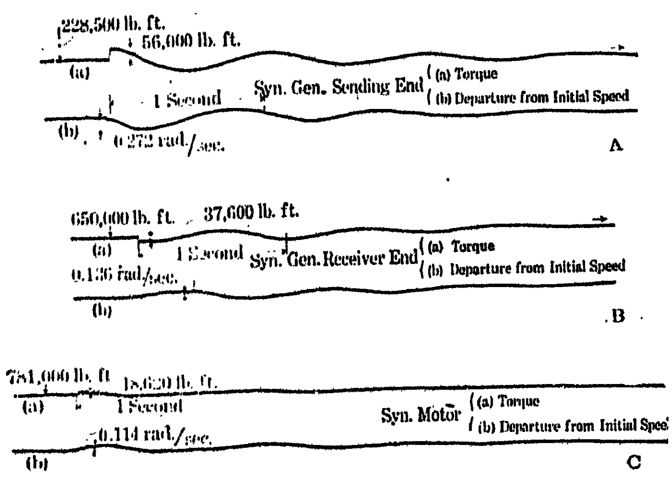

FIG. 7—TRANSIENTS FOLLOWING THE SWITCHING OUT OF A LINE SECTION INDICATED IN FIG. 5

During the above transients, the time elements of both the governor and the magnetic fields play a part. After load is thrown on a unit, it is a matter of seconds before the governor becomes adjusted to the new condition. Hence, regardless of the sudden load, the flow of water, or steam, as the case may be, is practically the same as before, and in studies of what happens in the first second or so, constant *flow* (not constant torque) is usually assumed.

The magnetic flux linked with the alternator field circuit also does not change in the first moment[7]. The armature currents due to sudden load automatically induce a corresponding m. m. f. in the field to sustain constant flux linkage. If there is no voltage regulator, the flux gradually dies down to steady state conditions, but during the meantime the reactance of the machine is less. It starts as transient reactance of relatively low value, which includes armature and field leakage, and ends as synchronous reactance, which is of relatively higher value and which includes armature leakage and armature reaction, but not field leakage. As already mentioned, this inherently stiffens the machine in the first moment. In other words, to speak of the spontaneous rise in alternator field current following a shock, whether it is a short circuit or a sudden application of load, or to say that the transient reactance applies, is merely to refer to the same phenomenon in different terms.

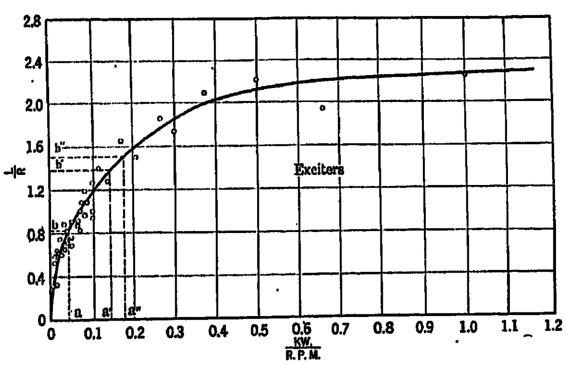

FIG. 8—CURVE INDICATING THE RELATION BETWEEN THE TIME CONSTANT AND THE SPEED AND CAPACITY OF EXCITERS

If there is a voltage regulator, then, as previously mentioned, it is a race between the rate at which the load comes on and rate at which the exciter can build up. As mentioned before, the combination of circumstances attending transients of this character are favorable in this connection. The alternator field current tends, by itself, to increase sufficiently to maintain constant magnetic linkages in the field circuit. So, the machine is not dependent, in the first moment of a shock, upon the exciter to increase the field. It does this itself, and the current tends to hold up for an appreciable time. This gives the exciter a chance. The period of oscilla-

7. "A Simplified Method of Analyzing Short-Circuit Problems", by R. E. Doherty, TRANS. A. I. E. E., Vol. XLII, p. 841, 1923.

tion of a system is of the order of one second, which means that the peak of the first overshoot in power would usually occur in about a half second. It is in this swing that the *inherent* field current rise, or the transient reactance, saves the situation and gives the exciter voltage a chance to reach the proper level by the time conditions have settled. And as already pointed out, the standard design of exciter has, in many cases, sufficiently low time element to adequately meet this condition. Where special attention is required in making the exciter more responsive—perhaps in the large, slow speed exciters—there are a number of ways in which this might be accomplished. The most obvious, and perhaps the simplest, is merely to decrease

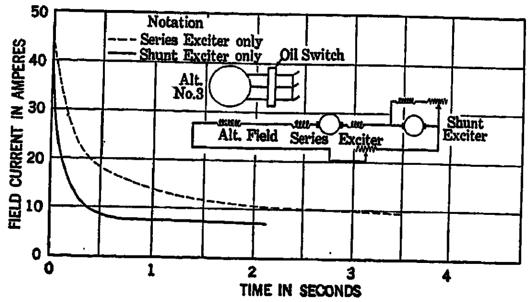

FIG. 9—EFFECT OF "SERIES EXCITER" IN LENGTHENING THE ALTERNATOR FIELD TRANSIENT

the duration of the transient in the same way the transient is shortened in any inductive circuit—by decreasing the value of the time constant L/R.

Such measures, if necessary, would apply to the larger exciters of low rotative speed—that is, machines of large volume. These have higher time constants because they have greater masses of copper and iron. To illustrate how these factors are related, Fig. 8 gives a number of points representing actual exciters over large ranges, showing the time constant plotted against kw./rev. per min., which, at given magnetic and current loadings, represents volume. It will be noted that these points lie well along the average curve. The exciters used in the tests fall at the points b a, b' a', and b'' a''.

Another and perhaps more efficient way of meeting the situation is to use the "series exciter" in the excitation circuit. This functions merely as a negative resistance, and thus neutralizes the effect of the ohmic resistance of the alternator field circuit. If it were not for the latter, the field flux of the alternator during a sudden swing in load would remain constant—that is, there would be no tendency for flux decay. So the alternator transient is lengthened by the extent to which the resistance is thus neutralized. This gives the shunt exciter a longer time in which to build up. Fig. 9 shows how the alternator field transient is lengthened by the series exciter. The total ohmic resistance was adjusted to the same value in either case.

Short Circuits. Short circuits are one of the most serious kinds of transients. This transient also calls into play all of the factors mentioned above. A three-phase short circuit on a branch of a system not only disturbs both the power and the magnetic balance of the generators, but also completely isolates the branch from the rest of the system until it is cleared. Loss of synchronism is usually expected in such cases.

A single-phase short circuit (which most of them are[8]) is not so serious, in that power flow is possible through the other phases past the point of short circuit. Whether the parts of the system break synchronism depends, among other things, upon the load at the time, the momentum of rotating masses, the duration of the short circuit, the electrical power transfer during the trouble, the restored voltage when the short circuit is cleared, and the amount of "induction motor" torque in the synchronous machines.

Long experience on existing systems is the most promising aspect of this question. Although now and then a case is reported where loss of synchronism follows a single-phase short circuit, it is rare where adequate relays with short time setting are used. This is a fact which cannot be overlooked in considering this important question. Calculations are usually made on the basis of conservative premises (as they should be) until basic data are complete; but even if such calculations indicate that loss of synchronism might occur oftener than good service could withstand, it must be remembered that experience rather indicates

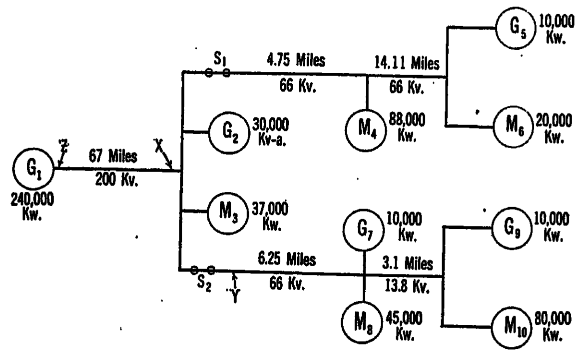

FIG. 10—TRANSMISSION NETWORK

the opposite. This is a problem on which sufficient detailed operating data have not been accumulated to afford adequate bench marks for calculation; and until this is accumulated, estimates must be no better than the premises on which they rest. Meantime, judgment, which is based on experience and such calculations as are possible, must be used in proposed undertakings.

An idea of the power oscillations following a single-phase short circuit at X on the system shown in Fig. 10 is given in Fig. 11. This is for a case in which the short circuit remains on the system, and the prime mover power is practically constant.

Many cases of transients similar to the cases referred

8. Particularly on high voltage systems in which the conductors are arranged horizontally.

to above, in which direct calculation is hopeless and step-by-step process is extremely difficult and often hopeless, can be effectively studied by Nickle's method, referred to above. In this, an equivalent electric circuit—involving no rotating apparatus—solves the equations, and the oscillograph plots the results.

With reference to all of the foregoing discussion of transients, while they may be much more difficult to solve than problems on steady state, methods of practical estimate and calculation are nevertheless available excepting for single-phase short circuits; but here it is less a question of method than of premises. Where direct mathematical methods fail, graphical methods can be used, as illustrated in the step-by-step processes devised by Bush and Booth.[9] Beyond this lies Nickle's equivalent circuit method.

Design

When the best estimates now available are made, it is found that, on the whole, the problem of increasing the

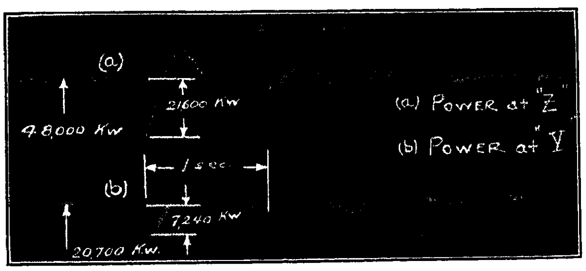

Fig. 11—Point Transient Following a Single-Phase Short Circuit at Point X on System Shown in Fig. 10

maximum power under all conditions of operation is principally one of designing apparatus and accessories that will give the greatest possible stability. It has been observed that this problem of stiffening the synchronous machines has been attacked along two lines, one relating to the design of the synchronous apparatus itself, the other to regulating schemes.

The problem of the designer of synchronous apparatus is to go to the limit in increasing the ratio of the field strength to armature strength, to the end that the armature reaction due to the load shall have the least possible effect in distorting or decreasing the magnetic field. The object thus sought is usually referred to, whether properly or not, as low synchronous reactance. From the discussion of field excitation under *steady state,* it follows that it is desirable to design the synchronous machines so that they will require at all times and loads as near as possible the field strength required by the maximum load, and to have this, in turn, as great as heating limits of the field will permit. Then, whatever the load, the machine is better prepared to take an additional load.

It is important to observe here that many generators for the usual commercial load of lagging power-factor are already designed to such a limit. These other measures for increasing the required field current are necessary in the present problem, because the power factor on long distance transmission lines is usually nearer unity than the ordinary commercial load, and therefore requires lower field excitation than the usual system load. In other words, what is thus attempted in design modification is, in reality, only to increase the stability or stiffness of the synchronous machines under this special condition of operation to that which it already possesses under the usual condition of lagging power factor operation.

The present problem, nevertheless, often demands more inherent stiffness than can be obtained by the above measures. This addition can be had only by increasing the size of the machine, which, of course, is both expensive and inefficient.

So the best that can be accomplished along the foregoing lines is hardly a satisfactory solution. It is an approach only, which, as it now appears, must be supplemented by effective regulating devices.

Regulation

This is the other general line of attack mentioned. The usual method of regulation is to automatically adjust the alternator field current by means of the vibrating type regulator operating on the exciter field to hold the bus voltage as near as possible to a constant value. Referring to Fig. 3, the function of this regulator is to cause the generator to pass from one curve to another along the line $e\,e$. There are, of course, an infinite number of such curves, and under steady state the alternator is functioning on some particular one of them. The *extremely important* point here is that although at any load under steady state the voltage is the same, *i e.,* along the line $e\,e$, nevertheless the machine is not operating on $e\,e$ as an inherent characteristic, but on one of the family of curves shown. In other words, although the machine operates at an intersection of $e\,e$ and one of the curves, it is on the latter, not the former. That is, the rate at which the voltage changes with respect to a power change is, for the moment, the slope $\frac{d\,E}{d\,P}$ of the particular curve, and this determines the degree of stability. The less the slope, the greater the stability, and, in the limit $\frac{d\,E}{d\,P} = 0$, there is the "infinite" generator. The slope of $e\,e$, of course, may be zero for any machine with a regulator, but that does not change the

9. "Power System Transients," Bush and Booth, Journal I. E. E., p. 229, March 1925.

inherent characteristic, on which the machine operates as illustrated in Fig. 3.

While it is not possible, in the nature of the case, to significantly change the slope of the characteristic by use of such a regulator, as explained later, it is possible to do it by other means of regulation. But before describing this, the general principle involved here which is not generally fully understood will be further discussed.

It is one thing to compensate for the effect of a phenomenon after it has occurred, and quite another to compensate *while* it is occurring. In the former, the thing happens and is then corrected; in the latter, it, in effect, does not occur. To illustrate the first: load is thrown on an alternator the voltage of which is controlled by a vibrating-type regulator. The voltage drops, then the regulator contacts close, which in turn starts the exciter voltage to build up, ultimately providing the field current necessary to restore the voltage. The time involved may be short, but the foregoing is nevertheless the sequence of events. The drop occurs and then it is neutralized. An exciter with low time constant may hurry the phenomena along, but the time-constant, even if decreased, still exists and it is interposed in the above sequence.

On the other hand, consider for instance the voltage drop in an inductive reactance of a feeder circuit. Add a series capacitive reactance of equal value. Then while the drop still exists across the reactance, it is, nevertheless, absolutely neutralized, at all instants, and at all loads, so far as the feeder circuit is concerned. The drop is compensated *as it occurs*, and the effect is the same as if it did not occur.

The difference between these two conceptions is the difference between what we have and what we should like to have in the principle of regulating alternators. If some one found such a scheme at once reliable and economically feasible for regulating alternators, there would be the equivalent of an "infinite" generator—one in which the change in voltage with change in load is zero, *i. e.*, $\frac{dE}{dP} = O$. And with apparatus so regulated at both ends of the line, the power limit of the line alone would have been attained. But such a scheme has not yet appeared in practical form.

To accomplish this in an alternator, two things are required. The armature reaction must be completely compensated by supplying opposing field ampere-turns of equal value in the proper space-phase and *at the time the armature reaction is occurring*. If this were accomplished it would be, in effect, as if there were no armature reaction.

The other point is that the leakage reactance must also be neutralized, which means that a voltage must be supplied which is in time-phase opposition to the voltage of the reactance. Theoretically, of course, this could be accomplished by series condensers of proper capacity, and this may sometime be practically feasible. Indeed, they may be used to neutralize the line reactance, as well.

To completely compensate for armature reaction, one is confronted by the difficulty both of applying the field ampere-turns in the right space-phase, and above all, of increasing it and decreasing it in exact conformity in time with the variations of armature reaction. However, while it is perhaps not to be expected that the ideal case will be realized practically, it is yet possible to partly compensate it by any scheme which will adjust the field current in rigid proportion to the armature current—which may be approximated by certain forms of self-excited machines.

But there appears to be a simpler way. Without expressing any assurance of practical application in the near future, it is noteworthy that a very substantial reduction in the effect of armature reaction has been actually obtained in a factory test by the use of the mercury-arc rectifier as an adjunct in the excitation

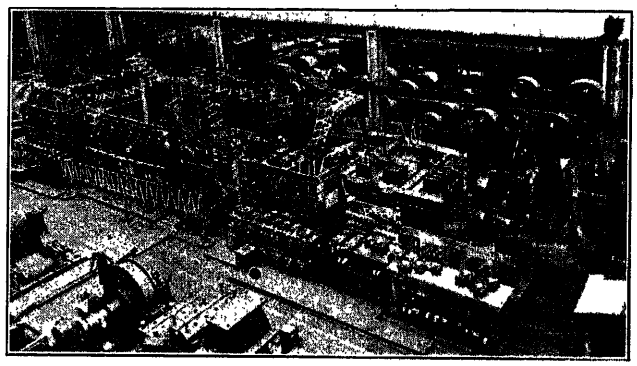

FIG. 12—GENERAL VIEW OF THE TEST

system. Its function is merely to supply field current in rigid proportion to the armature current, thus compensating for the latter *at the time it occurs*. By the nature of the circuits, and the variation of power factor, the space phase could not, in this particular case, be what was required. Nevertheless, the reduction in effective armature reaction, as evidenced by increased maximum power at the same voltage, under steady state, was of the order of 50 per cent.

Let the significance of this be clearly understood. Two maximum power (steady-state) tests were made on a minature 250-mile line with a 225-kv-a. generator supplying a synchronous motor of the same size. Fig. 12 shows a general view of the test set-up. One test was made with an ordinary vibrating regulator controlling the voltage of each synchronous machine, the other, with the rectifier as an adjunct. In the first, the power was gradually brought up to 120 kw. at 2000 volts at both ends of the line, 7.0 amperes on the motor field, 7.5 amperes on the generator field. This was the maximum power the system could carry. A further increase caused it to break out of step. Then the rectifier scheme was installed. Similarly the load

was brought up to the same point, *i. e.*, 120 kw., 2000 volts, 7.0 amperes field current on the motor, 7.5 on the generators. This power was *not* maximum. It was further increased at the same voltage to 154 kw., or an increase of 28 per cent.

This test is mentioned merely to illustrate the principle discussed above. The point involved is the difference between the slope of a curve and the value of the function itself. Analogously, if moving bodies were being considered, the interest would be not in the speed alone but also in the acceleration. It is not the value of voltage, but the slope of the voltage-power curve, that indicates the degree of stability. If a system controlled by vibrating regulators operating on the exciter is gradually loaded to imminent breakdown, the control can usually be taken over by hand and the same load held. In other words, although such regulators are highly effective in load transients in increasing the excitation as load is thrown on, they nevertheless do not significantly increase the steady state ultimate maximum power at normal voltage (p_3 in Fig. 3) over that corresponding to a fixed field current; and the reason is that, even with the regulator, the slope of the voltage power curve, in the first moment, is practically the same as if the regulator were not operating. And if it should be different during a sudden transient, it must ultimately return to steady state and thus to the slope corresponding to constant field.[10]

If this fact is not appreciated, it may be taken for granted, as frequently has been done before, that if the bus voltage is regulated, it may be assumed in calculations of maximum power that the voltage is *constant*. This assumption is justified only if $\frac{d\,E}{d\,P} = O$. It has even been proposed that by placing automatically regulated synchronous condensers along the line at given intervals, one may consider each of these sections as a unit, and that whatever power it is possible to transmit over one of them at the given voltage, can be transmitted, excepting losses, from one section to the other for a distance of, say, 1000 miles. Now this would be possible only with infinite generators and also infinite condensers, *i. e.*, such that the slope of the terminal voltage curve against reactive kv-a. supplied by the condenser is zero. To illustrate magnitudes, the maximum power of a 250-mile line at 220,000 volts, infinite bus at both ends, is about 225,000 kw.; of a 500-mile line, 130,000 kw. According to the proposal, with a condenser at the mid-point, it would be possible to transmit 225,000 kw., neglecting losses, over the entire 500 miles of line. Actually, a condenser at mid-point, of, say, 70,000-kv-a. capacity, would increase the maximum power only from 130,000 kw. to 156,000 kw. —not to 225,000 kw. This rather indicates what might be expected if the length were extended to 1000 miles.

10. An exciter with low time constant may expedite the regulation, but as long as the voltage must drop before the regulator contacts close, and the exciter field must be brought up before the alternator field current is changed, the compensation can not possibly occur at the time the armature reaction occurs.

Before concluding—regarding the foregoing discussion—it is well to mention again that consideration should not be confined to the cases of long distance straight-away transmission only. The problem in hand is one which, to a limited extent, relates also to power lines and networks of moderate distances, and the extent will undoubtedly become greater as the blocks of power to be transmitted continue to increase, or, indeed to tie connections of central station systems—to any, in fact, in which the power to be transmitted approaches the power limit of the system under the operating conditions. However, the problem involved in such systems, although more difficult to solve than those of single lines, is nevertheless the same, namely, to determine the power limits under various operating conditions, and to provide that these limits shall be as high as practically feasible.

What is the conclusion to be drawn from all of the foregoing discussion regarding synchronous machines? As to possible changes in design, the present indication is that no radical departure may be expected, that, at least so far as present proposals are concerned, reversion is made to the well established practises which have long since been followed in special cases where an increased stability or breakdown has been required: This is to to go to the limit in ratio of field strength to armature strength, and if that does not meet the required load, then get the remainder by merely increasing the size of the machine.

As to improvements by regulation, or more properly, compensation, it appears at this time that although there is possibly some hope for this in the future, the progress to date has been little more than the demonstration of the principle in actual test; but this affords sufficient incentive to actively pursue the investigation, when it is realized that for distances of transmission much above 300 miles the power limit with present equipment is such as to make these projects questionable from an economic standpoint, while, at the same time, the development of our resources will undoubtedly require the use of lines of this length in the near future.

Transmission Stability

Analytical Discussion of Some Factors Entering into the Problem

BY C. L. FORTESCUE[1]
Fellow, A. I. E. E.

Synopsis.—*The subject of stability has been much discussed lately, because it has an important bearing on future large power developments. In the early stages of a large program, such as the proposed superpower program, good engineering and common-sense dictate that each step should be very carefully considered from all points of view, since a blunder or failure to give proper weight to some important factor, such as stability, might set back the development program for many years.*

A brief historical review of the subject of stability follows; for those who are not familiar with "static" stability there is a review of the subject in the Appendix.

A criterion of stability is suggested based on present operating conditions, namely, that for reliability each unit of the superpower shall be at least equal to the best that has heretofore been obtained with similar power systems.

The necessity of a careful study of the characteristics of all machinery connected to the transmission line is pointed out. The necessity of proper inherent characteristics in generators and synchronous condensers is emphasized, and particular stress is laid on the necessity of proper volt ampere characteristics both inherent and with the exciter.

The action inside a generator during the transient following a change in load is discussed; it is pointed out that the true field is a resultant due to several magnetomotive forces in addition to that of the field circuit; the combined effect is a marked tendency to self-excitation, and inherent self-excitation would take place if it were not for the damping effect of resistance in the different circuits.

A brief review of other factors entering into the problem is given. These factors comprise inertia of moving parts, mechanical torque, speed of relays, circuit breakers, etc. The difficulty of correlating all these quantities is pointed out, and a basis on which it is practical to make computation is suggested.

Those who have not studied the subject of stability are recommended to read the Appendix before proceeding with the subject of transient stability.

The subject of transient stability is opened with a definition of stability of a power system.

The elements of the problem are discussed in some detail. The problem is one of obtaining the conditions of equilibrium, taking into account mechanical or applied torque, electrical or counter torque, inertia torque and damping factors, in addition to the electrical characteristics of the system. The action of a generator under suddenly applied load is discussed in some detail.

The "transient" stability of a simple system is discussed, use being made of a new diagram known as the power angle diagram which may be derived from the circle diagram as obtained for static stability. Three diagrams are required for the simple investigation, but the method may be elaborated to include all the factors affecting the problem including the characteristics of governors, exciter systems, and so forth.

The difference between the problems of switching operations, load swings, and short circuits is pointed out. In the last case the effect of different values of ground resistance is discussed at some length and also the effect of length of time before circuit breaker opens.

The necessity of obtaining reliable data on ground resistance with faults is stressed.

Throughout this paper the essentiality of delivering the necessary kilovolt-amperes to the line either by adequate exciter systems or by proper modification of machine characteristics in order to maintain a high order of stability is insisted on.

It is pointed out in the Appendix that while inherently compensated generators, synchronous condensers, etc., are future possibilities, our main concern is the problem of getting the most out of present day designs as our present day problems depend on these and not on something that may be commercially developed five years from now. Consequently the conclusions refer to means that may be made quickly available and the two most important are:

a. Improved inherent regulation of machines.

b. Increased speed of excitation.

THE problem of stability of transmission systems has come up for considerable discussion during the last few years due to the fact that it has an important bearing on the future development of power in this country, particularly in localities where there already exist large concentrations of power which it is proposed to tie together by high voltage transmission lines.

The connecting links between these large distribution centers and generating points must be such that the resulting unified system has at least as good a perform-

1. Electrical Engineer, Westinghouse Electric Mfg. Co.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

ance as regards maintenance and reliability as the best of its constituents, and as a matter of fact to fulfill the hopes of its advocates this resulting system should show a better performance.

A principle which common sense seems to dictate in the early stages of a development, of such magnitude as this programme represents, is to carefully weigh all the factors which go to make a successful system. It is not incompatible with the optimistic spirit, which is part of the make up of the engineering profession, to weigh every factor carefully before taking the first steps because so much depends on the success of the first part of such a program. A blunder or failure to give the proper weight to such a factor as stability might have very grave effects and set back the development program for many years.

The old saying that "a chain is no stronger than its weakest link" may well be taken as a guide during the initial stages, and I think that good judgment dictates that these first links of our superpower chain, especially those that introduce new sources of power, should be made as strong as we know how, at the present state of the art.

I wish to emphasize this point because there seems to be an inclination on the part of some engineers to underrate the importance of a careful study of stability, for the reason that large utilities today are operating satisfactorily and instability does not seem to disturb them. This reasoning is all the more dangerous because it is partly correct. The true reason why existing utilities are not troubled by instability is that when conditions of interconnection are met that tend towards instability, they are avoided either by giving up the advantages of interconnection or by strengthening the tie lines.

It is not safe to take past experience as a criterion on which to base superpower developments because of the necessity of maintaining service over the interconnecting lines, greater extent of the lines, and greater amounts of power to be handled by the lines, all of which factors are such as to increase the tendency to instability. As a matter of fact we know of a number of cases where instability has actually occurred and large systems have pulled apart causing more or less lengthy interruptions to service. How much more might the effect of the breaking apart of a large generating station from a superpower system be felt, especially in the initial stages, before the complete unified system has been achieved! I repeat, therefore, that it is not only good engineering practise but also good sense to make the first links of a superpower program as perfect from all points of view as is possible with the present knowledge of the art.

It is the object of the present paper to analyze the factors entering into the stability problem, confining the discussion to the consideration of simple cases in order to avoid undue complexity.

General Review of the Subject

The attention of the engineering world has been drawn to the phenomena of instability as a result of actual experience in operation. The early cases naturally had to do with links between generating stations in distribution systems. I can recall some early cases of instability due to short circuits in feeders connecting large generating stations which were the cause of a good deal of speculation.

More recently there has been a tendency to connect large utilities together with a view to interchanging power in case of emergencies. Unfortunately these tie lines have been frequently of the type very aptly defined as "shoestrings" and have failed to carry out the purpose for which they were intended. In other words these shoestrings in themselves were unstable and could not tie the systems together. In many of these cases, fortunately, the reason for the tie was more sentimental than real, and the systems tied together being self sufficient, no harm was done when they broke apart. The case of a superpower interconnection would be another story and a break apart might be serious.

We first became interested in this question as a result of a study of the possibilities of troubles due to connecting large hydroelectric generating plants through long transmission lines with large public utilities distributing power. This study has thrown a new light on this whole class of operating phenomena and a number of happenings which were mystifying in the past, in the light of knowledge gained by this study have very simple explanations.

To cite a few examples, we have all heard of the fading out of power from a hydroelectric source supplying a utility. We have also heard of power surges which appear to be of more or less harmonic character; that is to say, a generating plant has a period during which it alternately acts as a motor or generator. These cyclic changes may be relatively slow and will be indicated by the wattmeter which will swing in synchronism with the load changes. The system in such a case has already passed the point of stability although not infrequently the generator ultimately falls in step again. The effect on a large system may be quite serious as synchronous motors may be thrown out of step during the period of unstable operation.

In the case where the generating station has not passed the point of instability, it may oscillate about the point of stable operation for several seconds, this being evidenced by oscillation of the station wattmeter until the ultimate operating position of the generator rotors is reached. These characteristics will be further elucidated after the elements entering into the problem of stability have been considered.

The first study of a phase of the problem of stability was made by the late Dr. C. P. Steinmetz. In his paper which was published in the 1920 TRANSACTIONS of the A. I. E. E., he confined himself to the analysis of system troubles but did not give consideration

to its aspect as a possible limitation in high-voltage transmission.

The consideration of a superpower network extending over the Eastern States and perhaps eventually over a great part of the United States and Canada has emphasized the importance of a careful study of the factors influencing the stability of large superpower systems with a view to controlling and improving the characteristics of the various units entering into the problem.

I take it that a criterion of operation must be set up for each portion of the superpower program. It cannot all be carried out at once; therefore each portion must conform to some standard of operation. What is this standard to be? I feel that all public utility engineers will be unanimous in insisting that each portion of the proposed program when completed and in service will perform this service with at least the same reliability as the best that has been obtained in similar existing power supply systems. By reliability I mean freedom from interruption and ability to deliver load at the proper voltage.

The nature of the standard set up for superpower lines will influence not only the type of line construction used but also the characteristics of the generators and synchronous condensers. It may be necessary to look into the secondary transmission lines to insure that they do not prove to be the weak link in our chain. Where long transmission lines are involved, intermediate synchronous condenser stations will prove economical provided that condensers of proper design are used.

It is necessary therefore in studying the stability of superpower systems to consider also the characteristics of generators, exciter systems, condensers, etc., to ascertain what type of design will prove most suitable for superpower extensions and will insure the highest degree of stability. Other apparatus such as circuit breakers, relays, etc., will have an influence on the problem, but the generator with its exciter and the synchronous motor are the fundamental elements in the problem of stability.

Electrically both generators and synchronous condensers are extensions of the main transmission line with somewhat different characteristics. But, as we know, transmission lines differ in characteristics, and no appreciable error is incurred by ignoring the distributed capacity in low-voltage transmission while in the case of 220 kv. it becomes of supreme importance. The same thing is true of generators and synchronous condensers; these may appropriately be considered as transmission lines having reactive impedance (although saturation will affect the constancy of the reactance), if we have to consider only slow changes in load without regard to matters of stability; but when studying matters of stability, whether static or transient, both must be considered with reference to their exciter and damper windings so that the action becomes that of coupled circuits. The result of this is that any change in armature current sets up in the field current and damper winding changes in the currents which tend to annul the magnetic effect of the change in armature current so that the field tends to remain constant for a substantial period after the change takes place. If it were not for the resistance of field and damper windings, these transient currents would persist and the generator or synchronous condenser would be to a certain extent self-regulating. There would be a drop in terminal voltage due to the increase in load, however, due to the imperfect magnetic coupling between field and armature and this drop may be termed the leakage drop.

Since it is not possible to get away from resistance in the damper and field winding, recourse is had to an exciter system which builds up the field current faster than this induced current dies down. Thus the effect is the same as, or better than, what would be obtained if the field and damper windings had no resistance. It is possible to carry this method of compensation to the point where the terminal voltage remains substantially constant during sudden changes in load or other disturbances.

There are other ways of course by which similar results may be obtained, but these involve new developments whereas that cited above follows along standard well-tried lines.

The above, together with the transmission line, the characteristics of which are well known, constitute the electrical elements entering into the problem. There are other elements which come into our picture due to the fact that our generator, synchronous condenser, and the load are not only electrical transmission systems but also mechanical transmission systems having inertia and these systems are coupled with the electric system by a torque-speed or power coupling. This adds very considerably to the complications when we try to compute what takes place with a sudden change in conditions. We shall return to this subject later on when we look into the problem of transient stability in more detail.

I have enumerated above the physical and electrical characteristics of machines that enter into the problem of stability. In addition to this the problem is tied up with the action of the various relays such as those controlling the exciter voltage, the hydraulic relay devices controlling the gate opening, and the steam throttle governors, the relays controlling the operation of circuit breakers in cutting out sections of transmission lines when a ground or short circuit takes place. It will be obvious to engineers that to take accurate account of all these factors would be a hopeless proposition, so we proceed on the basis of ignoring such factors as appear not to influence the problem to any appreciable extent. For example, the assumption is usually made for ransient stability that the power input to the generators remains unchanged during part of the disturbance; this is justified due to the extreme sluggishness of hydraulic governors.

Transient Stability

Much has been heard in recent years of stability but no clear and comprehensive definition of the term has been published. Stability may be defined as the capacity of a power system to remain in equilibrium under steady load conditions, and its ability to regain a state of equilibrium after a disturbance has taken place. The first part of this definition is referred to in this paper as "static stability," and the second part as "transient stability." It should be noted that after a transient disturbance, the system will not necessarily seek the original state of equilibrium.

The problem of stability is one of securing a proper balance between mechanical input to a generator and its electrical output, and the electrical input to a motor and its mechanical output, the electrical quantities being dependent on the characteristics of the machines and of the system as a whole. It is, therefore, an exceedingly complicated problem, involving mechanical factors such as inertia, governors, gate speeds, etc., and also electrical factors such as machine characteristics, line constants, breaker operation, etc.

The natural tendency of a generator connected to a power system is to deliver electrical power equal in amount to the mechanical power delivered to its shaft less its own losses. This condition of equilibrium is satisfied when the counter-torque due to armature currents and field is exactly equal to the mechanical torque applied at the shaft by the prime mover. When such a situation arises that there is a difference in the mechanical and electrical torque, the generator either speeds up or slows down until a new position of equilibrium is reached; and during the transition stage, the inertia forces due to the moving masses act in a manner which tends to prevent any change in speed.

In thinking over these questions, it is well to consider all the aspects a generator or system of generators may take. It may be purely a generator or take on the characteristics of a synchronous condenser, or even of a motor. The torque on its shaft working as a generator compels it to deliver sufficient power to equilibrate the applied power. In attaining this state of equilibrium, moving from the initial position where the machine acts as a synchronous condenser (no external load) to the position where it acts as a generator, the rotor is accelerated, so that when equilibrium is reached, the rotor, considered as a mechanical cyclic system, has advanced in phase. This advance in phase is just sufficient to cause the equilibrating current to flow as in a simple transmission line, so that the power input and output diagram of the generator would be exactly the same as that of a simple transmission line, if it were not for the effect of saturation and the effect of internal magnetic coupling during the transient state. The phase advance of the rotor is just equal to the phase angle between the terminal voltage of the machine and the component of internal voltage due to the direct current in the field. This phase angle, however, is not the true angle of advance for the reason that the electrical torque depends upon the action between armature current and the actual field—not a fictitious field. The actual field is produced not only by the field current, but also by the armature current.

When a change in input or output of a generator occurs, currents are set up in the field circuit and

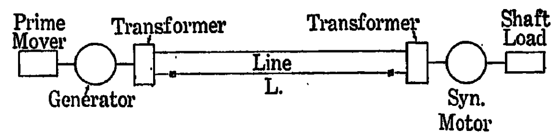

Fig. 1

dampers which tend to maintain field and the voltage generated thereby at their original value. At the same time, the rotor takes up a new position, and in so doing, inertia torques are introduced which must also be taken into account.

The proper value of voltage to take account of in matters of stability is therefore the voltage set up by the true field which is the resultant of the d-c. field current, induced field currents, damper currents, and the armature currents; this is the e. m. f. actually generated by the field and which is required to establish equilibrium between electrical and mechanical torques.

Let us analyze the problem with a simple system, assuming a generator supplying power to a synchronous motor over a two-circuit transmission line as indicated in Fig. 1. For the steady-state condition, there will be a phase angle between the internal e. m. fs. of the generator and motor. This angle is a function of the load, and in general varies in the manner shown in Fig. 3, which is known as a "power angle diagram." In the diagram, let P_0 represent a particular input to the generator. For this input, α_0 is the angle between the generator and motor e. m. fs. for the steady-state condition, or point of equilibrium.

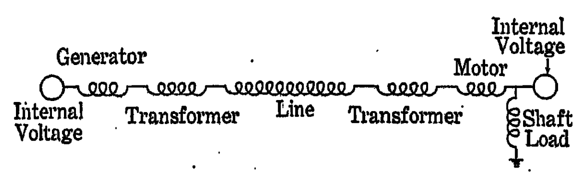

Fig. 2

It will be noted that it is possible to obtain another solution corresponding to α' which is, however, an unstable solution. Let us consider a small increase in the angle α beyond α'. This will cause a corresponding drop in the output, and consequently since the input is constant, the generator will accelerate and increase the angle of advance, the effect being cumulative. In the case of a small decrease in the angle α from α', the generator will slow down or move in the direction of α_0.

A similar analysis shows that α_0 is a point of stable equilibrium, because small displacements from that point will set up forces tending to restore the system to the point α_0.

It is evident from the diagram that the load can be increased to the value indicated by P_s which represents the static limit for the circuit assumed, and with the generator and motor voltages maintained. While

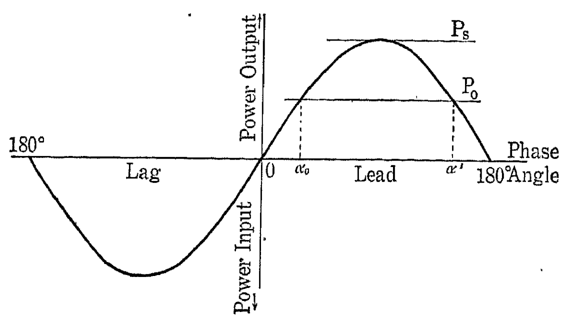

FIG. 3—ANGLE DIAGRAM OF SIMPLE POWER SYSTEM BASED ON CONSTANT VOLTAGES AT BOTH ENDS

there is a definite static limit dependent on the circuit characteristics and on the voltage conditions, there is no well defined limit for transient stability. In fact, it is necessary to specify both the load and the magnitude of the disturbance in order to determine the transient stability limit.

If the system is operating with the power input P_0 and a disturbance takes place, causing the angle α to increase beyond the value α', it will be unable to recover itself, even though the disturbing force has been re-

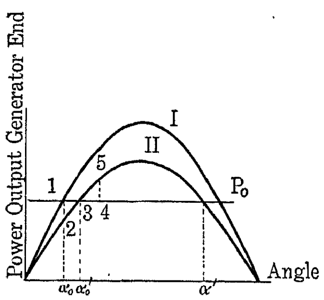

FIG. 4—ANGLE DIAGRAM OF SIMPLE POWER SYSTEM FOR SWITCHING OPERATION

Curve I Initial condition
Curve II Condition after switching

moved. In general, the disturbance will affect the generator and motor in different ways; consequently it will be necessary to employ two power angle diagrams in studying conditions during disturbances, one representing the generator end, and the other the motor end of the system.

The principal conditions of operation tending to produce instability in a power system are as follows:

a. Line switching
b. Load swings
c. System faults

As an example of line switching let us consider the simple system shown in Fig. 1 and Fig. 2 and assume that line L_1 is opened at either end. In this case the power angle diagram may be represented as shown in Fig. 4, for the condition before and after the switching operation. Let us assume that the power input to the generator is P_0 and that the original steady state angle is α_0. After the switching operation the new position of equilibrium will be reached at α_0'. When the system is operating at α_0 the opening of the line L_1 reduces the

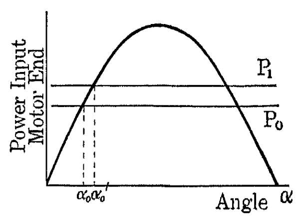

FIG. 5—ANGLE DIAGRAM OF SIMPLE POWER SYSTEM FOR SUDDEN INCREASE IN LOAD

power that will be taken over the system at that angle by the vertical distance between the power input curve and the new output curve. The power represented by the distance point 1 to point 2 represents that consumed in accelerating the generator rotor. Because of this acceleration the angle α will increase along the new curve towards point 3. As it approaches point 3 the accelerating force will decrease and the velocity will increase until at point 3 the accelerating force will be zero and the velocity a maximum. As a result the rotor

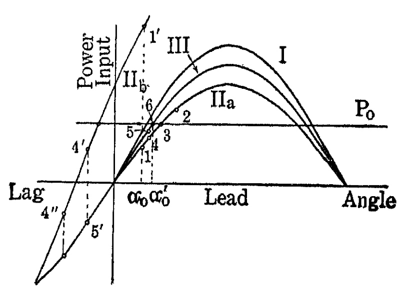

FIG. 6—POWER ANGLE DIAGRAM FOR SHORT-CIRCUIT CONDITIONS

Curve I Initial condition
IIa Low resistance fault
IIb High resistance fault
III Final condition after fault is cleared

will overshoot towards point 5, a retarding force being set up which will increase as the point 5 is approached. At point 5 the velocity will be normal and the retarding force a maximum tending to bring the rotor back to point 3. The amount of the overswing will be such that the area 1 2 3 equals the area 3 4 5 except for the damping action due to losses. Because of the losses the swings will become smaller and smaller, oscillating about

the final position α_0'. For the case considered the system is stable since the overshoot does not carry it beyond the point α'.

Load swings differ from switching operations in that the circuit constants remain substantially the same and the input and output vary, whereas, with switching, the input and output remain substantially the same and the circuits constants are changed. Considering again Fig. 1, and assuming that the load is increased as indicated in Fig. 5 from P_0 to P_1, if the increase is suddenly applied, the prime mover governor not responding immediately, the increment of power will have to be supplied by the kinetic energy of the system, slowing it down. This action will cause the governor to act and restore the speed to normal by increasing the input to the system to correspond to the new output. Initially, however, there will be a disturbance due to the falling back of the motor with respect to the generator increasing the angle α between them, and there will be an overswing similar to that described in connection with the switching operation in Fig. 4. The generator and motor will oscillate with respect to each other but together will slow down towards the new angle of equilibrium α_0'.

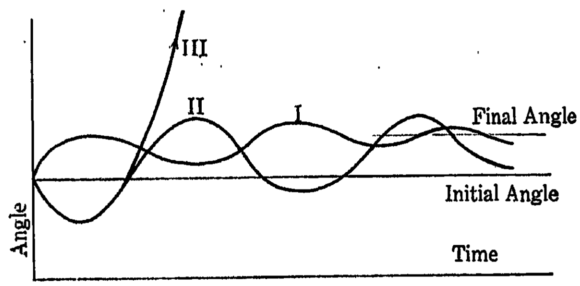

FIG. 7—ANGLE-TIME DIAGRAM OF SIMPLE POWER SYSTEM

I Switching Conditions—Stable
II High resistance fault—Stable
III High resistance fault—Unstable

The change of power input by governor action will in general necessitate the use of several power angle diagrams to properly represent the intermediate steps.

Short circuits present considerably more complications than switching operation and load swings due to the fact that three distinct networks are involved:

a. The original condition prior to the application of the short circuit.

b. A second condition while the short is on the system.

c. A third condition when the fault has been cleared, usually by a switching operation.

The second condition is what makes the short circuits radically different from switching operations or load swings. The short circuit may increase or decrease the power input according to whether it is a high- or low-resistance fault. A high-resistance short circuit usually occurs in the form of a fault to ground in a grounded neutral system. There is a certain resistance for which the power increase will be a maximum.

The effects of the two types of shorts are indicated in Fig. 6. Let Curve 1 represent the power angle diagram for the initial conditions with P_0, α_0 as the point of equilibrium. Curve I I_a will represent the conditions with a low resistance fault applied to the system. An oscillation will be set up about point 3 between 1 and 2 as described previously when considering switching operations. The circuit breaker may open at almost any point during this oscillation, for example at point 4. The opening of the breaker immediately modifies the circuit conditions and a third network is set up of which the power angle diagram may be represented by Curve III, the power output being changed from point 4 to point 5. In general the transition from the network of II_a to the final network of III will be accompanied by a second oscillation due to the fact that either the angle initially will not correspond to α_0', the angle of equilibrium, or the velocity will not be such as to satisfy the condition of equilibrium; the system will therefore oscillate about the point of equilibrium, point 6 in the diagram.

In the case of a high resistance fault it is possible for the power output of the generator to be greater than the input as indicated by the Curve II_b. In fact power may be drawn from the receiver end of the system to supply part of the energy absorbed in the fault, for which condition the angle becomes negative. The sequence of events is similar to that previously described for the low resistance fault. It will be noted that stability is indicated in case the breaker opens at the point 4′ because the energy absorbed during acceleration (area under P_0) is less than the energy that can be given up during retardation (area above P_0). Pull out would occur should the breaker open at 4″ instead of 4′.

It is obvious from these considerations that the fault resistance is of prime importance in the consideration of short circuits. Unfortunately there is very little information available at the present time concerning the resistance of faults under high current conditions.

In the preceding discussion an attempt has been made to give a general picture of the phenomena of stability. Certain simplifying assumptions have been made which in the more general cases will require modification; for example, the mechanical inputs and outputs of machine are assumed constant. When the actual values are known as a function of time, suitable correction can be made. In this connection it may be pointed out that the stability limit for transient disturbances could be increased if the governors were made to regulate the input to the generators to correspond more closely with their output. Another simplifying assumption made in the above discussion is that of constant internal voltage of the machines. The effect of this may be corrected for by drawing up several power angle curves for different voltage conditions.

In the determination of the angular swings of the system and the stability limit, it is necessary to employ the point by point method of analysis, all the forces for

each point being in equilibrium. The computation of the changes in the values of internal voltage during transient conditions is best accomplished by the "two reaction method" which permits the utilization of different time constants for the two components of main field flux. By this method it is possible to take into account the effect of cross-magnetization and also the effect of the excitation system. The two reaction method also permits the determination of the mechanical rotor angle, which must be taken into account in the consideration of the inertia effect.

Power angle diagrams do not show time; therefore, for the final results, it is preferable to use curves, with time as abscissas, since stability depends upon factors which are functions of time. The angle between the e. m. fs. at the two ends of a system or the variation in the angle as a function of time gives a very satisfactory criterion of stability. These angle time curves will have the general form indicated in Fig. 7. Curve I shows a switching operation; Curve II and Curve III show a short-circuit condition with a high-resistance fault. Curve II shows the breaker opening at such a point that stability is obtained and Curve III shows the breaker opening at such a point that instability results as indicated by the continuous increase in the angle.

The object of this discussion is to review the principal factors entering into stability and to provide an adequate visualization of the problem. It is beyond the scope of this paper to go into the detailed calculations of the magnitude of system disturbances and stability limits. In this respect it serves as an introduction to a more detailed paper by Messrs. Evans and Wagner which is being prepared for the Midwinter Convention in 1926.

In the above rather cursory analysis of the factors involved in the problem of transmission stability I have tried to stress several important points which I repeat below:

1. Stability is a characteristic of an entire power system—not of any particular tie line—and in the determination of limits, it is necessary to have a complete diagram of the system with full data on connected machines, loads, etc. Care should be taken to select for consideration operating conditions which are likely to be the most severe from the point of view of stability.

2. The standard of service in a superpower system must be of the highest order. While it is recognized that stability cannot be expected under all abnormal conditions, in my opinion the stabilty criterion should be that synchronism be maintained under single-phase faults to ground followed by the switching out of the faulty section.

A method of analyzing stability is indicated, based on so-called "power-angle" and "angle-time" diagrams. These diagrams take into account both the electrical and mechanical transients by a point to point method. The changes in machine fields are computed by Blondel's two-reaction method, as this permits the separate determination of the two components of flux, which have different paths and different time-constants.

CONCLUSIONS

In conclusion, particular attention is called to certain factors entering into the problem such as characteristics of machines, time required by relays and circuit breakers to open, speed of operation of governors, resistance in the ground faults, and earth connections.

As a result of the above analysis the following methods of increasing stability suggest themselves:

a. Improved inherent regulation of machines which can be obtained without greatly increased cost.

b. Increased speed of excitation; this possibility was discussed at the Philadelphia meeting of the A. I. E. E. in connection with the paper by Messrs. Bush and Booth.

c. Modification of the prime-mover governor more closely to regulate the input to the generator in accordance with the requirements of the transient, thus reducing the mechanical oscillations.

d. Development of a high-speed breaker and relay system to reduce the oscillations subsequent to the opening of the breaker.

e. Reliable data on ground resistance are very much needed, particularly under conditions of high fault currents. I would like to enlist the cooperation of public utility engineers in obtaining this information, as the value of ground is one of the controlling factors in the problem of transient stability.

f. The calculation of transient stability is, at best, a very tiring and long drawn out job. In view of the importance of making such computations in the case of every important branch or connection of the proposed superpower system, every effort should be made to reduce the labor involved in these computations. If an artificial model can be devised which will supply all the factors in their right relationship with one another, such a method of solving problems will be welcomed. A purely mathematical solution seems out of the question as the problem when reduced to the simplest form involves elliptic functions. Very few engineers are sufficiently familiar with these functions to be at ease in handling them.

I wish to express my appreciation of the help extended to me by Messrs. R. D. Evans and Powell in writing this paper and by Mr. Dovjikoff in making the sketches and checking the text.

Appendix

Review of the "Static Stability"

INTRODUCTION

In the papers presented at the 1923 Midwinter Convention at Philadelphia by my colleagues and myself we confined our attention to the phenomenon of stability which has been termed static stability. There was some criticism of these papers on the grounds that

they did not cover all there was to be covered in regard to stability of transmission systems. I think that I have said enough as to the elements that enter into the problem to indicate how hopeless would be any attempt to cover the subject generally in one paper and I may say in passing that this paper makes no pretense to go into details on any part of the problem but is more in the nature of an introduction to a paper by Messrs. Evans and Wagner which is in preparation for the next Midwinter Convention. The static stability problem appeared to be the stability problem in its simplest form and it seemed to us appropriate to begin the study of stability by a series of papers on this limit to the operation of transmission lines. That this is one of the important limits in operation under emergency condition is evident from the following statement by Mr. H. A. Barre in an article by him published in *The Electric Journal*, June, 1925.

In designing a long high-voltage transmission line, careful consideration must be given to its stability, because the economic load and the ultimate carrying capacity of the line are of the same order. Studies of the Big Creek line indicate that, with only a single line in service, the ultimate carrying capacity under steady load conditions should be about 180,000 kw. at the generator end. On one emergency, this condition was actually reached. One whole line was taken out of service on a Sunday for maintenance work. About six o'clock in the afternoon the load built up very rapidly to 183,000 kw. when the synchronous apparatus at the two ends of the line went out of step. The voltage dropped

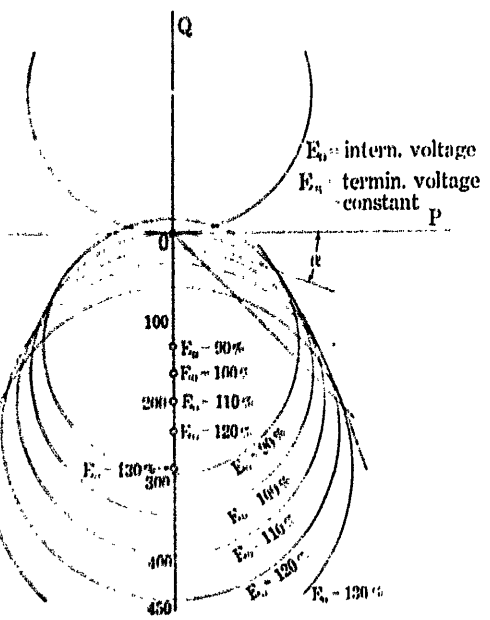

Fig. 8

nearly to zero, hovered there for awhile and then gradually built up to normal. About fifteen minutes later the load again built up to 183,000 kw. and the whole performance was repeated. Soon after the voltage came to normal the second time the other line was switched into service and there was no further trouble. So far as we know, this is the first time that a long high-voltage line has passed through this unstable condition.

The static stability limit will depend upon two conceptions. The first has to do with inherent stability and is based on the assumption that the regulator system is too sluggish to act before the transient current which tends to counteract the demagnetizing effect of the armature current has died out. This is the same as assuming constant excitation. The second considers the proposition that the dying out of the transient is so slow that the regulator has, in general, time to get into effect before the field has had time to change appreciably, so that the limitation is set not by the synchronous impedance of the generators motors and condensers but by the leakage impedance, which should also include the

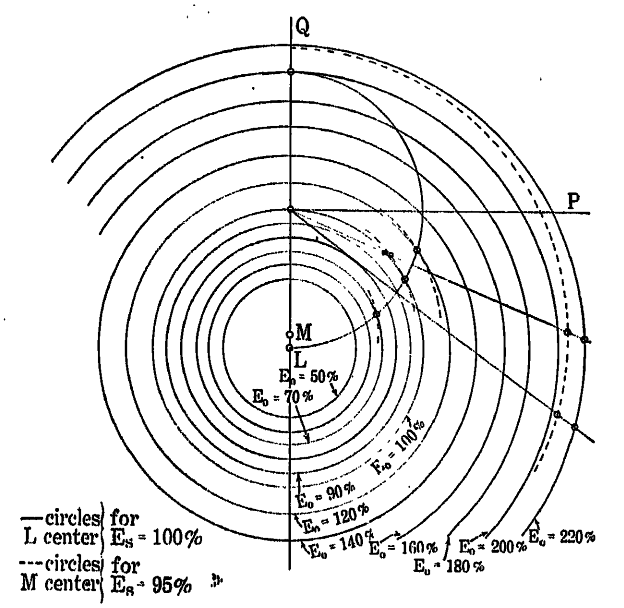

Fig. 9

leakage set up by the induced rotor currents. This is the same as assuming constant internal voltage.

There has been a great deal of discussion as to the proper basis on which the static stability should be determined. It has been argued that the synchronous impedance is the controlling influence but tests up to date indicate that this assumption is much too pessimistic; the second condition appears to be a reasonable assumption provided the rate at which excitation is required is not in excess of the ability of the exciter system. Several propositions that are necessary to a proper understanding of the subject will now be given consideration.

1. *An inherently compensated generator has no power limit.* This of course is an ideal that would be impossible in practise since internal heating would always be present in a practical machine. Several methods have been proposed for the internal compensation of generators, which are theoretically correct, but from a manufacturing point of view impractical. Even if such a generator were practicable the limitation of prime mover governors would make it of doubtful value. It is, however, a useful ideal to keep in mind when considering problems of stability.

2. *A generator having a fixed value of excitation will have a power limit depending on the nature of the load.* This power limit depends upon the value of the terminal voltage obtained under load and is therefore larger for leading power factor loads than for lagging power factor loads. The quantity entering into the terminal voltage regulation is the synchronous impedance which will vary with the field saturation and therefore is a rather crude quantity to use, but it serves quite well in illustrating the problem of stability qualitatively. If the load varies in power factor in such a way as to maintain constant terminal voltage as well, the load limit is quite definite and is obtained by a circle diagram of the same form as that for a simple transmission line. If we make a family of such circles (Fig. 8) using different values of terminal voltage, the loci for loads of constant power factor are lines drawn from the origin cutting the circles and stopping at the envelope returning back again to the origin. The power limit when the power factor is fixed is therefore the value of the load indicated by the intersection of this line with the envelope.

3. *A generator having its internal voltage fixed will have a load limit depending upon the nature of the load.* The same comments as in the case of proposition (2) applied here with the added statement that the actual load limit will depend upon the ability of the exciter system to maintain this constant field during changes of load.

Static Stability of Generator and Load. (*A dead reactive load*). A generator excited in the usual way will be stable for loads having only fixed resistance and inductance and the terminal voltage of the generator will be maintained constant within the limits of the capacity of the exciter system. During the transient stage, following an increase in load, there will be a fall in terminal voltage due to the leakage reactance of the generator, but this will be corrected as the exciter builds up the field. During the first transient stage, the field is kept practically constant by the corrective currents flowing in the field circuit and in the damper windings. The relation between internal voltage of the generator and the load may be easily obtained (Fig. 9) by drawing the power output circles for constant terminal voltage of the generator with varying internal voltage, drawing the locus for a constant power factor load which is a straight line drawn from the origin inclined at $\cos^{-1} \alpha$ to the axis of X. It will then be seen that, while the diagram indicates no limit, if we superimpose on this diagram a similar diagram for the same values of internal voltage but for a terminal voltage slightly less than the original value (Fig. 9), the power circles of the last diagram corresponding in internal voltage to that of the first will not always be outside the first, showing that an increase of admittance will result, after a certain load, in decreasing power at a given power factor, with the internal voltage considered constant. The condition when the first circle is wholly outside the second takes place in the neighborhood of $E_0 = 2\,E_s$ and for values of E_0 above this there will be a tendency for the voltage to dip on application of additional load of any power factor.

Dead Load with Leading Power Factor. In the diagram just given, the generator is assumed to have practically no resistance, so that the center of the concentric system of circles lies on the Y axis; the following construction, however, holds for generators and motors having resistance. If a circle is drawn having its center at the origin passing through the center for $E_s = 100$ per cent, this circle is the locus of intersection for the circles having the same value of E_0 but slightly lower value of E_s with the system of circles representing $E_s = 100$ per cent.

The Cartesian equation of the system of circles given in Fig. 9 is given by

$$(P_s - E_s^2\, g)^2 + (Q_s - E_s^2\, b)^2 - E_0^2\, E_s^2\, (b^2 + g^2) = 0 \tag{1}$$

In this equation the values $E_0\, E_s$ are parameters, fixed values of these quantities giving one of the members.

Let us consider the system E_s = constant; the system is a system of concentric circles with center at the point $P_s = -\,g\,E_s^2$; $Q_s = -\,b\,E_s^2$. If now we consider E_s to vary somewhat from its fixed value, let us say diminish slightly, the family of circles for the diminished value of E_s will intersect the other family of circles at certain points which will have significance because at these points the value of power delivered will be stationary because with increased admittance the voltage will tend to drop as fast as the current increases, the value of E_0 being considered fixed.

To obtain the locus of these intersections, differentiate (**1**) with respect to E_s and equate to zero; this gives us

$$2\,g\,(P_s - E_s^2\, g) + 2\,b\,(Q_s - E_s^2\, b) + E_0^2\,(b^2 + g^2) = 0 \tag{2}$$

Eliminating E_0^2 between (**1**) and (**2**) we have

$$P_s^2 + Q_s^2 + E_s^4\,(b^2 + g^2) - 2\,E_s^4\,(b^2 + g^2) = 0$$

or

$$P_s^2 + Q_s^2 = E_s^4\,(b^2 + g^2)$$

This is the locus of intersection of contiguous circles; E_s = constant when E_0 is the parameter and represents the loci of intersection of contiguous members of the family when E_s is considered to decrease slightly. It is a circle having the origin as center and which passes through the center of the family of concentric circles.

The circle touching the origin represents the condition of equality between internal and terminal voltage and all the circles that lie within this circle represent the condition of load in which the internal voltage is less than the external voltage; this condition can only occur at leading power factor. It will also be observed that where a line from the origin touches one of the circles, this represents a double solution and all such solutions lie within the circle locus. All points of intersections between constant power factor loci and the circles for $E_s = 100$ per cent contained in this region within the circle locus represent loads that are essentially stable

in character, whereas the values obtained outside this region are inherently unstable, for the reason that an increase of load does not take place naturally since the circle for a slightly lower terminal voltage and the same value of internal voltage as existed before the increase falls within the corresponding circle for the original terminal voltage and this same value of internal voltage. This illustrates the reason why under certain conditions the natural regulation of a system may become quite bad so that there is a tendency to produce a slump in voltage when additional load is thrown on, so fast that the exciter cannot keep up with it. If, however, the characteristic of the load is such as to give more leading current, or what is the same thing less lagging current, with decrease in terminal voltage the stability is greatly increased.

Induction Motor Load. This does not differ essentially from the dead inductive load discussed above but the tendency to slump in voltage after a certain load may be so marked that the exciter will not be able to cope with it and as a result the motor may fall in speed below its pull-out point.

Synchronous Motor Load. Assuming that the terminal voltage is maintained constant, we shall have three methods by which this may be done:

1. By generator field alone, synchronous motor excitation being kept constant.
2. By synchronous motor field alone, generator field being kept constant.
3. By varying both generator and synchronous motor field so as to get the best results.

The circle diagram for the input to a synchronous motor with constant terminal voltage is similar to that of a generator with constant terminal voltage except that the center of the circles is on the opposite side of the origin. In fact if the internal impedance of the two machines is the same, the motor circles are the images of the corresponding generator circles with respect to a line passing through the origin at right-angle to the line joining the centers of the generator and motor circles which also passes through the origin.

For the condition of constant internal field in the motor, the circle corresponding to this field strength is the locus for the power input to the motor. The generator circles passing through these points give the generator field required to maintain the terminal voltage at the given value. It will be readily seen that a limit to the amount of power that can be delivered is quickly reached.

For the condition of constant field of the generator the proper generator circle is taken, and the same comments apply as for the first case.

Next let us consider the case in which both machines are regulated; this must follow some specific scheme as both machines cannot regulate to maintain voltage.

For the condition of constant power factor, the power factor line gives the locus of the points of intersection of motor and generator power circles which will give the proper field strength for this condition with each value of load.

Mathematically, if unity power factor is taken, for an ideal generator and motor, that is to say, machines having no resistance, there is no limit to the amount of power. Actually the limit is set by the exciter system, for when the internal or field voltage reaches a certain value indicated by the circle of intersections, more power cannot be taken by the motor or delivered by the generator without an increase in the field strength of either or both machines. This may be shown graphically by drawing the circle diagram for the two machines based on this value of field voltage and varying terminal voltage; it will then be seen that the only solutions possible under these conditions give lower values of power. Therefore, further demand on the system must be supplied by an immediate increase in field strength or else the characteristics of the motor changed so that it delivers more leading current as the voltage decreases.

This condition does not necessarily imply instability but it indicates that without the aid of the exciting system a further increase in load admittance may be sufficient to cause the two machines to fall apart and this might also happen if the exciter system were too sluggish.

The point I wish to emphasize in this discussion is that the stability of such systems depends on the ability of the system to inherently supply the necessary wattless power required to meet the sudden demand for power; fortunately, except under abnormal conditions, the demand is relatively slow and plenty of time is given for building up the field to supply the necessary wattless power.

The interposition of a transmission line still further limits the load that can be transmitted between the two systems. I wish to take this opportunity to correct a statement that has repeatedly been made to the effect that the distributed capacity of a transmission line compensates the reactance of the line. It is true of course that at light loads it causes a rise of voltage along the line but it also increases the range of regulation and increases the tendency toward instability. It does not cut down the size of synchronous condensers as much as is popularly believed because the total range of regulation of the machine is increased, requiring lagging kv-a. at light loads and leading kv-a. at heavy loads.

To determine the static stability of a system consisting of generators, transmission lines, and synchronous motors on the assumption that the voltage is held constant at the sending and receiving end of the transmission line, the circle diagram of the transmission line at the receiving end is drawn, and the power circles of the input to the motor are also drawn to include the step-down transformer impedance on the same scale and superimposed on them. The same thing is done for the sending end with the generator. Several values of field voltage of the motor are then taken and the

corresponding values for the generator are obtained in the usual way from the second diagram. The circles for constant field voltage of this value with varying value of terminal voltage are then drawn with the corresponding value of transmission circles for both sending end and receiving end assuming simultaneous reduction in terminal voltage at each end. If the value of power input remains stationary for a slight decrease in terminal voltage the point of instability is indicated. Another procedure is to construct the circle diagram for the whole system including the generator and the motor leakage reactances checking up with the complete generator diagram, that is to say, the input of the generator considered as part of the transmission system and the output of the motor considered the same way. If maximum output is indicated for either machine with constant internal voltage this will be the point of instability.

I have dwelt some time on the problem of static stability because it is a necessary introduction to the main problem, that of transient stability, as it contains a number of the important elements required in the consideration of the transient stability problem. I have particularly considered the synchronous motor for the reason that the characteristics of most supply systems can probably be fairly well expressed by a modified form of a synchronous motor load.

Fig. 1 shows the generator, transmission line, and synchronous motor in the form of a diagram. Fig. 2 shows the simplest form of power system in the form of an electrical diagram. In this diagram the internal voltages of the collective machines, reduced to a common voltage, are expressed by a figure in a circle. It is apparently not a far cry from the first form of circuit to the second. *The main requirement is to obtain an equivalent system which will give the same voltage wattless power characteristics as the system under investigation.* It is important to obtain reliable data on the characteristics of systems that are to be connected to a high-voltage transmission line as the character of the loads will have a great deal to do with the stability of the transmission line.

Discussion

FUNDAMENTAL CONSIDERATIONS OF POWER LIMITS OF TRANSMISSION SYSTEMS

(Doherty and Dewey)

AND

ANALYTICAL DISCUSSION OF SOME FACTORS ENTERING INTO THE PROBLEM OF TRANSMISSION STABILITY

(Fortescue)

Seattle, Washington, September 16, 1925

P. H. Thomas: The paper by Doherty and Dewey emphasizes even more than those of previous date the part played by the terminal apparatus in stability of operation. Of course, it matters not what the electrical equations show as to the theoretical capacity of a long line if when terminal apparatus be applied to supply power and receive load the combination is unstable to operate, as might easily be the case with loads anywhere nearly approaching the theoretical capacity of the line should the usual present designs of synchronous apparatus be used.

However, we have this fact to remember: the capacity of the line as shown by equations is an absolute limit without power of change until some of the physical constants of the line are changed, while the limitations of the terminal apparatus are merely matters of economy and cost. The very long transmission line may well represent $125 per kilowatt of delivered power, while the terminal apparatus costs much less, at least so far as the securing of suitable stability characteristics is concerned. If the choice lies between limiting the maximum duty of the long line and adding to the terminal-apparatus cost, the latter course is to be chosen, generally speaking.

The proposal to correct by simultaneous and automatic support of the field magnetizing turns the falling field strength when a line is suddenly overloaded is a significant and important proposal and the analysis offered is clear and to the point. No doubt there are other ways of accomplishing this same result.

The 28 per cent greater load carried by the rectifier-excitation test as reported over the regulator test in the experimental line is very encouraging. At the critical point of the regulator test it is evident that a further increase in power transmitted would require a higher actual field magnetism both on account of the higher load and on account of the less favorable power factor that the line will demand and temporarily also greater on account of the initial drop in terminal voltage. It should be noted that the motor end must drop behind on the increased load before anything at all happens in the electrical circuit. But this regulator cannot act until the voltage actually has dropped and by that time the system has dropped out of step and the regulator never gets a chance to try. With the rectifier, however, an excess of exciting power is added in the field before the motor drops back to the new position for the greater load and the field is ready to support the necessary additional power current.

I think the authors are a little too severe in their reflections on the line charging current. While it may be true that with certain set-ups due to the limitations in machines, the total theoretical maximum power which can be delivered by the line will be slightly less over the line having its normal electrostatic capacity than over a hypothetical line with no capacity, nevertheless it is not likely that charging current will be a detriment under practical operating conditions.

The statement that a certain 300,000-kv-a. station may deliver more power over two lines than over three and none at all over nine lines is not so significant as it might seem. It simply means that, for the three or nine lines, the system is so proportioned that machine capacity which should be devoted to carrying kilowatts is absorbed in carrying charging current or that the ratio of synchronous condensers to number of lines is not favorable. Either the kv-a. of the station should be increased by building the machines to operate at a lower power factor or shunt reactance or other means used to neutralize a part of the charging current. It goes without saying that it would not be economical to use an unnecessary number of lines.

With regard to the authors' Fig. 3 and the discussion of the part played by field current, I should like to point out that, with a heavily loaded line, there is very little choice as to power factor, for this is definitely fixed by the load and the terminal voltages and will inevitably be high at the generator end. However, there is this advantage of power factor near unity: The effect of added lagging current due to increase of load on the drop from internal impedance within the machine is small with high power factor. This is an important matter.

Since the power factor changes with every change in load on the long line, the curves of Fig. 3 should be supplemented by other curves showing the effect of such change of power factor, and these modified curves might easily show a different best

relation between low-power-factor and high-power-factor loading from that indicated by the uncorrected curves.

One other point: the authors state that the scheme of using divided line conductors to reduce reactance and increase capacity has not found favor partly because of the increased charging current. As I see it, this increased charging current is, on the whole, no disadvantage, for on any useful loading it greatly improves the line power factor. While it is true that leading current will tend to reduce the field current setting in generators, this is a matter affecting only the performance of the generator, subject to correction in a number of ways. If the rectifier excitation scheme proposed in the paper or any equivalent scheme is available, this objection to the high charging current disappears. Meanwhile the reduction of line reactance which accompanies the increase in capacity with divided conductors means an increase of substantially the same proportion in the maximum load the line will carry, assuming the percentage of line resistance loss to be kept constant. With a 20 per cent increase in line capacity in a 350-mi. line and with a favorable line power factor, any generator difficulties from the additional charging current would no doubt be cared for in the same suitable way. As a matter of fact on any full loading no charging current would appear at the terminals as the reactance energy of the line would absorb it.

F. L. Lawton: In the paper by Messrs. Doherty and Dewey, considerable emphasis has been given the question of voltage regulation of the synchronous equipment of transmission systems. This, however, is in line with the papers[1] and discussions[2] at the last Midwinter Convention when the subject of high-speed excitation was given prominence.

As the method of regulation outlined by Messrs. Doherty and Dewey—viz., the use of mercury-arc rectifiers as adjuncts in the excitation circuits of transmission-system synchronous equipment—is probably the most promising development looking toward increased system stability, it seems wise to discuss it somewhat in detail.

During the course of various investigations of the stability of power-transmission systems, it was realized that considerably greater stiffness in a system would be desirable; also, that such greater stiffness could be secured by the use of excitation systems having a time constant much smaller than usual. As a consequence, Messrs. Fortescue and Wagner discussed results they had obtained with a so-called high-speed exciter, at the 1925 Midwinter Convention.[3]

While it is true that less voltage fluctuation will occur during load or short-circuit transients, when the synchronous machines of a power system are excited by high-speed exciters, it must be remembered that such exciters are inherently not different from any other exciter, so far as behavior under transient conditions is concerned. That is, when lagging load is suddenly added to a generator so equipped, the terminal voltage drops. The decrease in voltage energizes the Tirrill-regulator relay which short circuits the exciter field resistance, permitting the generator field current to increase.

After an appreciable time, the alternator terminal voltage is restored to the normal value. *Inasmuch as the alternator armature reaction is not compensated for at the time it occurs, the power limit*, for slowly applied loads, of any system equipped with high-speed excitation equipment, *is no greater* than for a system provided with normal exciters. Furthermore, as it is now realized that a power-transmission system is inherently stable for any load up to the steady-state power limit, no matter how added, there is comparatively little advantage in the use of such high-speed exciters beyond the reduction of voltage fluctuations.

1. Power System Transients, V. Bush & R. D. Booth, A. I. E. E. JOURNAL, March 1925, p. 229.
2. Discussion, A. I. E. E. JOURNAL, July, 1925, pp. 766-771.
3. A. I. E. E. JOURNAL, pp. 767-770.

Let us consider the case of an alternator equipped with an ordinary excitation system with the addition of a mercury-arc rectifier, excited from the line, as an adjunct. When a lagging load is thrown on such an alternator, the rectifier supplies an excitation current proportionate to the line current, varying simultaneously with it. *As a result of the simultaneity of action, the alternator armature reaction is at all times counterbalanced by a proportionate field current.* That is, *the armature reaction is effectively neutralized.*

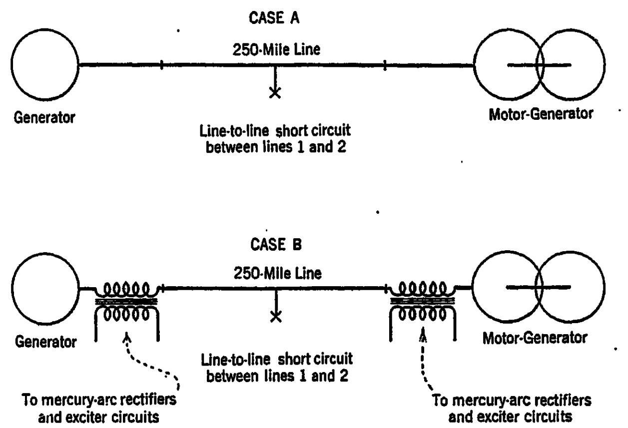

FIG. 1—SCHEMATIC DIAGRAM OF SYSTEMS USED FOR SHORT CIRCUIT TESTS

As Messrs. Doherty and Dewey have indicated, a reduction of about 50 per cent in effective armature reaction was obtained. While this reduction was not so great as theoretically possible, nevertheless it resulted in an increase of 28 per cent in the steady-state power limit of a 250-mi. miniature system.

It is worthy of note that this gain was maintained during tests involving the sudden addition of loads when, if ever, it might be expected that the rectifiers would be ineffective. Not only were increased power limits obtained, but practically no decrease in voltage occurred when a large load was suddenly added to a system equipped with mercury-arc rectifiers; but as much as a 20 per cent momentary drop in voltage occurred when the same load was added in the same way to the system using normal Tirrill-controlled excitation systems.

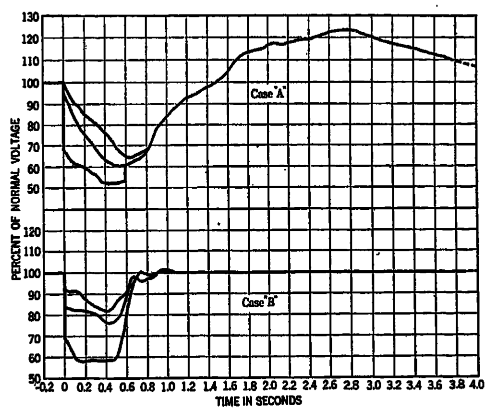

FIG. 2—VOLTAGE DISTURBANCE DURING A SINGLE-PHASE, LINE-TO-LINE SHORT CIRCUIT ON A 220-MILE SYSTEM

The advantages of rectifiers as adjuncts in the excitation circuits of transmission-system synchronous equipment are probably most marked in the case of system short circuits. Tests similar in all respects except the excitation circuits have been made on the systems illustrated by the accompanying Fig. 1 to determine the maximum amount of power which could

be transmitted with stable operation under the condition of a half-second, single-phase, dead, line-to-line short circuit at the mid-point. It has been found that the system with rectifiers could carry 50 per cent greater load with much less fluctuation in voltage. To illustrate the comparative voltage fluctuations, Fig. 2 herewith has been prepared. Case A, Fig. 2, shows the three receiving-end voltages for the system of Case A, Fig. 1, while Case B gives the corresponding voltages for the other system. While the duration of short circuit for Case B was somewhat less than for Case A, the load being carried prior to the short circuit was 35 per cent greater and the initial short-circuit current 50 per cent greater. In spite of these unfavorable factors, the decrease in voltage was less with the system of Case B; virtually no over-voltage occurred when the short circuit was cleared. With the system of Case A, considerable excess voltage occurred some time after the clearance of the short circuit; a much greater time was required for the restoration of normal voltage.

The above facts illustrate the very important advantages which may be gained by the successful application of mercury-arc rectifiers in the excitation circuits of the generators and other large synchronous equipment of power-transmission systems. There appear to be no disadvantages beyond the possible necessity for oil circuit breakers of a somewhat higher rating, at a few points.

In conclusion, it appears that the only high-speed excitation system which will enable the securing of increased system power limits, for all conditions of operation, must be such that the armature reaction of the synchronous machines is effectively neutralized by the addition of field ampere-turns in the proper space-phase simultaneously with the occurrence of the armature reaction.

I believe the mercury-arc rectifier, properly applied as an auxiliary in the excitation circuits of synchronous units, is the first development giving promise of *a real increase in the power-transmitting capacity of transmission systems.*

S. B. Griscom: The statement by Messrs. Doherty and Dewey that, during transients, "the synchronous apparatus becomes inherently more powerful" is not clear. The field transient accompanying an increase in armature current is of such a nature as to tend to prevent the main field flux from decreasing, but it does not strengthen it. Actually, the magnetic flux starts to decrease immediately upon an increase in armature current, and consequently the field becomes weaker. Another way of stating it is that the very presence of the additional field current, flowing through the field resistance, is *due* to a decreasing field flux.

Under "Regulation," it is stated that the slope $\frac{d\,E}{d\,P}$ of the voltage-power curve determines the degree of stability. I should like to point out that such a criterion does not take into consideration the mechanical transients which are always coincident with an unstable condition, and it may, therefore, lead to erroneous conclusions. In the region where $\frac{d\,E}{d\,P}$ approaches infinity, $\frac{d\,P}{d\,t}$ approaches zero, because $\frac{d\,P}{d\,\theta}$ is limited by the mass of the synchronous machines. For this reason $\frac{d\,E}{d\,t}$ becomes very small and, in the case of large systems having heavy masses, is undoubtedly much less than the combined time constants of voltage regulators, exciters, and generator fields, for a normal building up of load. The maximum load which may be carried under steady conditions is therefore considerably increased by the use of voltage regulators. This conclusion agrees in a general way with similar conclusions by the authors, although in some cases apparently contradictory statements and data are introduced.

In particular, it would be expected that the tests reported at the bottom of page 982 should show nearly equal maximum loads for the two forms of excitation used, provided the load was built up by increments that were small as compared with the stored energy released during a small shift in phase of the synchronous motor. It is also probable that a load consisting of a large number of small synchronous units would cause the power transmitted over the line to change more slowly, giving more time for the regulator to function.

In a similar manner, voltage regulators on synchronous condensers located at intermediate points on a transmission line, by holding the voltage constant under a gradually increasing load, should permit a much greater power to be transmitted than the same line with the same total condenser capacity located at the receiver end only. The maximum power limit of such a system, as given by the authors, appears to be entirely too low for a condition of steady loading. During transients, the maximum load that can be transmitted safely is considerably reduced but will still be much higher than a straight-away line for the same disturbance.

The use of synchronous condensers at intermediate points has been discussed a number of times, but the advantages apparently have not been fully appreciated. Condensers are usually installed for the purpose of voltage regulation and since the receiving end of the line is usually the only point where voltage regulation is needed, all of the condensers are located there. However, the real function of the condensers is to supply the reactive energy loss due to the flow of current through the line reactance. This loss is distributed practically uniformly over the length of the line and consequently a reduction in copper loss and a slight decrease in total condenser capacity may be effected by installing a portion of the condenser capacity at an intermediate point. Such an arrangement would tend to reduce short-circuit currents, particularly at the receiving end which is usually a point of high power concentration. Location of condensers at intermediate points should not prove unduly expensive or difficult because, in the majority of cases, switching stations and attendance will be required for line sectionalizing. Machines of suitable characteristics and equipped with a high-speed excitation system, or compensation, are of particular advantage for this application. It should be noted, however, that such features are made desirable principally by the conditions obtaining during transients and not for steady loading.

R. D. Evans: Probably the most interesting data submitted by Doherty and Dewey are the results of the calculations shown in Fig. 2 of their paper. This figure shows the "Maximum power which can be transmitted 250 mi. at 220,000 volts, shown as a function of the capacity of synchronous apparatus, and the number of transmission circuits."

The curves of Fig. 2 were presented for the purpose of showing the importance of the charging kv-a. of lines in reducing the power limit and they serve this purpose in an excellent manner. However, the important effects of the charging kv-a. in limiting the maximum power appear only when the synchronous capacity is small in comparison with charging kv-a. of the transmission line. This condition of operation would suggest that a lower transmission voltage would give higher actual power limits.

The condition in which the generating capacity is small per line is of relatively minor importance because the power to be transmitted per circuit at 220 kv., 250 mi., must be of the order of 75,000 to 125,000 kw. in order to be within the economical range at the present time. With this relation in mind, it is advantageous to compare the results shown in Fig. 2 for different kv-a. capacities of synchronous apparatus. In the first place, it will be noted that the characteristics of machines assumed by Doherty and Dewey are such that the rating of the machine can-

not be developed because the power limit of the system is approximately two-thirds of the nominal capacity of the synchronous machines; that is, 100,000-kv-a. capacity on this line will show a power limit of approximately 70,000 kw. per circuit. If the characteristics of the terminal equipment are altered so that the reactance is approximately two-thirds, and the field current approximately three-halves of the values assumed, the power limit would be increased to approximately 100,000 kw. This condition would correspond to the curve given in the paper for 150,000 kv-a. in synchronous apparatus. Similarly, if a power limit of 150,000 kw. were to be obtained, the machines should have approximately somewhat less than two-thirds the reactance and more than three-halves of the excitation of the machines assumed by Doherty and Dewey. In other words, the power limit per circuit can be increased up to at least 125,000 kw. per circuit by the use of machines of suitable characteristics. The significance of this discussion is that the desired static limit may be obtained by merely modifying the authors' assumptions so as to employ machines of lower reactance and higher excitation. In the absence of alternatives, which are still in the development stages such as special regulator and compensator schemes, the use of machines of suitable characteristics is a practical solution available at the present time for producing quite marked increases in the stability of systems.

In view of the position taken by the authors that static limits are the only limits that are worthy of computation, it is interesting to compare the calculated static stability limits as given in Fig. 2 of the paper with the practical results of experience on an actual 220-kv. system. For a single-circuit, 250-mi. transmission system operated at 60 cycles, with approximately 200,000 kv-a. in synchronous apparatus at each end, the static limit is calculated to be about 115,000 kw. In the June issue of the *Electric Journal*, H. A. Barre states that the static limit of the Edison System was reached under a particular emergency condition. For this condition, power was transmitted from 240 to 270 mi. over a single circuit at 220 kv., 50 cycles, with approximately 200,000 kv-a. in synchronous apparatus at each end, and the static limit was found under actual operating conditions to be 183,000 kw. One would expect that the static condition on the Edison system would correspond well with the other condition mentioned previously, the greater length of the 50-cycle system and the probably greater transformer impedance roughly compensating for the increased frequency upon which the calculations were based if the authors had assumed machine characteristics corresponding to those of the synchronous apparatus on the Big Creek system. What is the explanation of this discrepancy from 183,000 kw. on an actual system to 115,000 kw. as given in the calculated results? In the first place, the exact assumptions used by Doherty and Dewey are not stated, and it may be that the explanation lies in them. If such is the case, the Fig. 2 should be interpreted with care. A possible explanation may lie in the fact that probably synchronous motor load was assumed in the Doherty and Dewey calculations, whereas the actual system involves a certain amount of resistance load which would cause the power to fall off with drop in voltage. The influence of the load characteristics is not mentioned, so far as the writer can recall, at any point in the paper, and it may be that this factor is of importance in the particular case of the static limit on the Edison system and under certain conditions would undoubtedly be of great importance in other cases. The explanation of the discrepancy between the calculated maximum limit and the maximum limit obtained under actual operating conditions is, of course, very important. It is worth pointing out that actual static limits may be appreciably in excess of calculated limits which do not take into account all the factors affecting stability.

S. W. Copley: These two papers indicate that the methods of calculation used do not differ greatly fundamentally, but there is some difference between them in the assumptions made as to the values used for the characteristics of the terminal apparatus. This difference causes some important divergence in views as to the power-limit figures. Possibly Doherty and Dewey are too pessimistic in their assumptions with respect to the reactance of terminal apparatus, or they have not given enough credit to the action of voltage regulators in holding the system together. Both of these points warrant further investigation. Machines of lower reactance can be designed and a regulator which has higher speed characteristics is a possibility. There are certain drawbacks to the application of such machines and regulators, but if the limits of power transmission must be raised the disadvantages can without doubt be overcome.

C. L. Fortescue: Messrs. Doherty and Dewey have presented with clarity the characteristics of synchronous apparatus which are of importance in the problem of stability. In dealing with the stability of machines of this type, they have laid much stress on the fact that high power factor is detrimental to stability, as it involves low excitation or, what is the same thing, low internal voltage. While undoubtedly at times, transmission lines reach very low loads in which the excitation is correspondingly low, I do not know of a single case in which a system was thrown out of step by a sudden increase of load or a short circuit due to low excitation. I believe that the explanation which I shall give later will account for the fact that instability under such conditions is practically unknown.

While I believe we should keep such cases in mind as elements of the problem, I feel that the authors have over-emphasized their importance and may, therefore, produce a false impression in the minds of those who are not sufficiently familiar with the problem. A properly designed transmission system will make provision for the generators not to supply all of the charging current at light load, and, at heavy loads, the generator power factor will be normally lagging. Two transmission lines properly designed with the proper size of generating station and with proper provision at the receiver end and intermediate points to take care of the line reactive-volt-ampere requirements will always transmit more power than one line. I state this fact not because I believe the authors intended to convey the opposite impression but because the emphasis they lay on certain features of generators and synchronous motors might easily convey the opposite idea to the minds of those who are not closely in touch with the problem.

I had felt encouraged when I read the statement made by the authors on the fourth page, column one, and in the first part of column two as to the importance of excitation, though I will take issue with them in regard to part of the statement by referring to a discussion on excitation in last Midwinter Convention by several of my colleagues in which the possibilities of high-speed excitation were discussed at some length and with considerable emphasis. Later on in their paper I was disappointed to find that the authors had reached the conclusion that high-speed excitation would not fit the bill but inherent regulation was what would be required. Again I must take issue with them in this matter and state that in my opinion they have reached an erroneous conclusion and their error is mainly due to their failure to perceive that the so-called static-stability problem is in reality one of transient stability.

I shall first show by means of a simple mechanical model that if generator and motor are provided with perfect regulators, no matter what their characteristics, they will furnish power up to the stability limit of the line itself. The model which I have in mind is quite simple and was devised by S. B. Griscom. If two sticks pivoted about one point are connected at the two ends by an extensible elastic string such that its linear extension is proportionate to its tension, and if torque be applied to one member, the restraining torque on the other member will represent the power output of a line. The applied torque is the power input. The above applied to a line having no losses

but having reactance and distributed capacity. This assumption involves no appreciable error in considering the actions that cause instability because the resistance of the line and generators has only a small effect on the stability problem. One may picture one of these pivoted members attached rigidly to the shaft of a motor and the other to the shaft of a generator. The motor drives the generator at constant speed, using this device as a mechanical transmission. As the generator load increases, the elastic connection would be extended in such a way that the sine of the angle between the two members will increase in proportion to the load. If we keep on loading the generator, the angle between the two members will finally become a right angle, at which point the mechanical transmission system will have reached its maximum ability to transmit power and the system will become unstable.

Now the internal voltages of the generator and motor may be represented by two additional sticks (as shown in the accompanying illustration) as extensions of the transmission line beyond this angle. The terminal voltages are kept constant; that is to say, the length of the original two pivoted sticks. As the angle is increased, the elastic line is kept straight by increasing the sticks representing the generator and motor internal voltages. Using this model, it can be shown that the torque at the generator will reach its maximum when the two members representing the terminal voltage of the transmission line are at an angle of 90 deg. with each other.

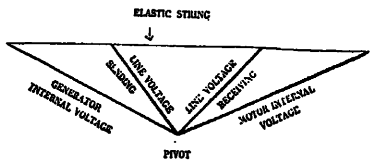

FIG. 3

I have made no restrictions as to the characteristics of the generators and motors except in the matter of losses as in the case of the transmission line, but it is easy to show by means of the model that the rate at which the internal voltage must be increased with increase of load is very much influenced by the internal characteristics of the machines, and if we make the internal leakage impedance low, we shall not require to have as great a range of excitation.

Objection may be raised that ideal excitation systems do not exist and that commercial regulators are too slow. The explanation resides in the fact that the problem is, in reality, not one of static stability but one of transient stability. You must remember that instability involves a change in angular position and this means a change in angular position of the generator rotor and the motor rotor as well as of the line terminal voltage. The electrical angle and mechanical angle are, you might say, irrevocably tied together and to deliver power to a motor through a line at a given excitation requires that they must take up a definite angular position with reference to each other. In my paper, I have pointed out that the angular relation is a continuous function of the power and is therefore suitable for analytical work whereas the voltage at the terminals is a discontinuous function and is not suitable for analytical work.

The fact that the angular positions of the rotors must change with change of load introduces the natural period of the system into the problem of voltage regulation and this means also that sluggishness of the hydraulic or steam governor may have some advantages. If the load is increased, the motor slows down and so does the generator. In slowing down, the motor supplies part of the increased load by inertia. The generator supplies part of the increase in transmitted load by inertia at a slightly lower frequency, so that matters are improved from a stability point of view, since, during this stage, only part of the increased load must be transmitted and also because it is transmitted at an appreciably lower frequency. While this is going on, the regulator has had time to get in its work and if the angular change is not too great, the voltage regulator will catch up before the angular displacement has reached the point where the system will pull apart at the increased value of load. Theoretically, this may be carried out close to the limit of stability of the line, providing the load increments are not so great as to cause large swings.

The authors have made no mention of the effect of the characteristics of the load and have merely touched on the improvement to be obtained by changing the generator characteristics, dismissing it with a statement that it will prove too costly. I wish to take exception to this statement and to say that such changes can be made, with a small increase in cost over that of standard generators and the increase in the ability of the system to transmit power will more than counterbalance this added cost. Such generators are immediately available and, with specially designed high-speed exciters, will permit of operation of transmission lines with a high stability limit.

In regard to the problems of internally compensated machines, much progress has been made along these lines, but since it is still in the development stage, very little can be said about it at present. It is possible to compensate a generator completely and even to extend this compensation to cover the impedance of transformers so that the generator has the characteristics of the infinite system of which Mr. Doherty and Mr. Dewey speak in their paper; but there are grave questions to be considered in the application of such machines. The rapid retardation and acceleration, caused by short circuits, and the subsequent clearing of the lines may produce mechanical stresses of great magnitude. In all probability some limiting device will be needed to limit the amount of current that can be delivered above a certain value.

Regarding the matter of transients due to short circuits, I agree with the authors that experience has shown that in existing systems with suitable relay protection, short circuits do not constitute a serious problem in operation. However, they make the statement that experience is the best guide and that calculations are always made on the basis of conservative premises and are therefore too pessimistic. The transient condition under short circuit will undoubtedly be the factor which will determine the ultimate rating of a transmission line and it behooves us to avoid being so conservative that our results are pessimistic.

I believe that we can or will be able to compute, with a fair degree of approximation, the results of a short circuit either to ground or between phases if we are provided with proper data as to ground resistance and load characteristics. I am further willing to go on record that we shall be able to install apparatus that will enable us to approach within a reasonable distance of the effect of an infinite system, not only on a straight-away transmission but also for one using intermediate synchronous condensers so that, with the latter system, the stability will be determined by the weakest section.

The automatic voltage regulator is not a hopeless problem for it is assisted by the fact that it takes time for the system to change its angular position whereas the terminal voltage changes instantly. Moreover, the internal reactions are resisted by inherent flow of exciting current. Therefore, the voltage regulator has time to act before the system gets beyond control.

P. H. Thomas: Mr. Fortescue, with his usual skill, has developed generalized equations for showing the theoretical limits of stability in electric systems containing synchronous machines.

The most difficult and illusive part of the problem of stability is the determination of the numerical value of the parameters of stability in particular cases and especially for the pendulum action or the tendency to overswing when a change of load in a

system or its equivalent requires a new position of equilibrium. The principles involved are well understood and at least one analytical and one electric analog method have been proposed. These, however, are merely methods of overcoming the mathematical difficulties of the solution and still leave untouched the difficulty of properly evaluating the factors of losses and damper currents.

As is well known, any damper current set up by an advance or retreat in the position of the rotor with regard to the revolving field of the stator will tend to reduce, temporarily, the forces driving the rotor toward its new position of equilibrium and similarly, if the rotor over-shoots, these damper currents tend to restrain the over-swing. If sufficiently powerful, these forces may render the swing of the rotor dead-beat. The conditions governing the effect of these damper currents, which will usually be of very low frequency, should be fully studied to see what can be done therewith to restrain the overswing.

These damper currents should be controlled by the resistance of the damper rather than its reactance, but subject to this limitation the damper resistance should apparently be as low as possible. The field winding, having by far the greatest weight of copper surrounding the field poles, would naturally have the most effective damper action.

While Mr. Fortescue has given a definition of stability which is entirely logical, we shall ultimately need something further, viz: a standard test or criterion to be satisfied by any particular system to insure reasonable continuity of operation.

It is yet too soon to offer such a criterion for actual adoption, but ultimately something in the nature of an overload to be taken at a certain power factor, or a drop of voltage (taking account of both ends of the line) that must be sustained without falling out of step, will be required.

It is gratifying that much has been done to render the terminal apparatus more responsive to its duties—but still more is desirable and no doubt possible, on account of the dominating importance of the cost of the line as compared with the cost of regulating and exciting means.

R. E. Doherty: I agree with the general point of view expressed by Mr. Fortescue—namely, that the lack of any great amount of trouble from instability up to the present time should not be interpreted as evidence that such a thing is not possible with longer lines and greater power, that, in any study of the problem, all elements of the system, including generators, exciters, condensers, lines, etc., and not merely one element of it, should be considered, and that the problem involves two fundamentally different "states" of operation—"transient" and "steady"—during which the operating characteristics of the apparatus are different. I also agree with the general exposition regarding the angle-power relations, only in so far as it gives a physical, qualitative picture of the phenomenon. I strongly endorse his appeal for reliable information regarding ground resistance and would add an appeal for recorded data and system experience during single-phase short circuits. And, finally, I endorse the view that the mathematical, or even graphical, determination of stability of such system networks as comprise our modern power systems is quite beyond the range of practical possibility. For these cases an equivalent system from which the required values can be obtained by test becomes necessary—just as for the same reason, it is necessary to thus determine short-circuit currents in complicated networks.

Such methods are available; the equivalent system proposed by C. A. Nickle[4] affords a valuable means of studying the power oscillations during transients, and the scheme proposed by Spencer and Hazen[5] affords a means of testing steady state power limits with practical accuracy. The latter method assumes sine-wave relation between power and angle, and is, therefore, roughly correct for maximum power studies. Nickle's method, however, in its present state of development, assumes linear relation between power and angle, and is, therefore, limited in this particular application to a study of the behavior of the various components of the system during those transients which do not involve power swings beyond the point where the linear relation ceases to hold. However, there are many interesting and important phenomena bearing on stability which can thus be determined, and if a circuit element giving the sine-wave relation is found, the maximum power can also be determined. The company with which I am associated is now completing the development of both of these facilities. While, of course, further improvements are ahead, the present development provides a very helpful aid, and, in my opinion, is a significant step forward.

There are a few points in the paper with which, if I interpret them correctly, I do not agree. They are relatively unimportant with respect to the general problem to which I have referred above, but have importance only in numerical calculations. I refer to the author's statement that the steady-state limit depends upon the leakage impedance and not upon the synchronous impedance. Making due allowance for saturation, which, in effect, reduces the impedance, the steady-state, ultimate power limit at normal voltage is determined by synchronous impedance, not by the leakage or "transient" impedance. A steady-state, hand-controlled test, giving a family of voltage-power curves (as in Fig. 3 of the paper by Mr. Dewey and myself) shows the same power maxima as determined by automatic regulator tests, and as calculated, using synchronous reactance. While it is possible with an automatic regulator, as it is not by hand control, to throw on suddenly loads equal to the ultimate maximum steady-state power, it is nevertheless not possible, according to our tests and conception of the problem, to carry significantly more than that by using a regulator actuated by the alternator terminal voltage and operating on a shunt- or compound-wound exciter of quick response. This is discussed fully in our paper.

In discussing the group of papers by Mr. Fortescue and his colleagues at the Midwinter Convention in 1924, I stated power limits which "in the present state of engineering knowledge" I considered to be justified. I said: "We must neither gamble that a voltage regulator will be able to insert a supporting prop under an otherwise falling system, nor depend for stability during load transients upon possible momentary favorable conditions due to momentary and field transients." Now the intensive study and investigation of the past year and a half has shown what we did not then know—that, up to the ultimate maximum power value, as determined by tests under hand control, the regulator can be depended upon to insert "the supporting prop," but not beyond that limit. I understand the author's statement to be that the regulator makes it possible to carry a constant load significantly greater than the above maximum; with this I disagree.

I do agree with the author that the object sought with an excitation system is to obtain the same characteristics as would be afforded by a machine which would inherently maintain constant flux linkages—one in which the field and damper resistances were zero. To say the same result would be obtained by an exciter of quick response which holds the alternator field approximately constant is in all respects parallel to the statement that if the terminal voltages at both ends of a line were held approximately constant by a regulator (as they can be, even by hand control, with gradual increases of load) the ultimate maximum power would be that of the line alone; *i. e.*, all limitations in the generator would thus be compensated, which obviously is not true. Yet the two cases essentially involve the same elements. It can be shown[6] that, following a load change, the flux change of

4. Oscillograph Solution of Electro-Mechanical Systems, by C. A. Nickle, JOUR. A. I. E. E., p. 1277, Dec. 1925.

6. Exciter Instability, R. E. Doherty, A. I. E. E. TRANSACTIONS, 1922, page 767, eq. 30.

the alternator field, $\frac{d\phi}{d t}$, is not zero, but essentially negative, unless a series negative resistance is introduced in the alternator field circuit. A method for obtaining this is described in our paper. A shunt- or compound-wound exciter, of however quick response, does not have this characteristic. Fortunately, however, for any load up to the ultimate steady-state limit at normal voltage, the ordinary exciter and regulator usually suffice; and this steady-state limit cannot, so far as our study and tests show, be increased by speeding up the exciter magnetically.

R. J. C. Wood: The main reaction I get from these papers is a feeling that perhaps we are using the wrong term when we talk about instability. We are not, ourselves, putting up the money to build these big systems, and I think that anything which unduly suggests a weak point in transmission should be avoided. I do not mean by that we are to conceal the truth in any way, but there is a psychological effect produced by the word "instability" which I do not think is produced when we talk about power limit.

What we are getting at is the power limit of a system. There are various things which limit that power; the current may be so great that the wire will fuse and fall in half, or it may be this "instability" that we are talking about.

If you go out to buy an automobile you take the automobile out and try it and you run it up a hill and the hill is of increasing steepness. After a time that car just lies down and quits. You have not an unstable automobile; you simply have reached the limit of its ability. Perhaps you kill the engine; perhaps you spin the hind wheels. That might be an illustration of the generators falling out of step.

It would be better if we could think and speak of this more in terms of power limit; everybody is familiar with the idea of a limit of endurance, both humanly speaking and as regards apparatus and machinery.

Roy Wilkins: I am employed by a company owning an interconnected system of upwards 8000 mi. of line 60-kv. and over, and with a total generating capacity of a little over 880,000 kv.-a. The connecting rotating load is about 2,000,000 h. p. At different times there have been tested 110-kv. lines up to 500 mi. in length in operation and carrying load, and loops as long as 350 mi.

I should like to point out certain road signs in the line of "don'ts" for people who, in the actual power industry, take up the study of power limits or instability as it has been called. First, don't worry about anything except the actual operating conditions. You will find trouble enough without running into any weird combinations which are impossible operating conditions. Second, don't expect to simplify the problem and still check the performance of a complete transmission system, because in a transmission system, every piece of connected apparatus has certain characteristics. These characteristics are all in their proper places, proper order, and proper values. Any simplification means a certain amount of error.

At the present time, there is too little known about circuit-breaker operations, corona, WR_2, impedance, load character, and load power factor, together with certain cases of trouble as grounds, etc. As a passing note, nobody, at the present time, knows exactly what "load power factor" is. I haven't been able to measure it in a year and a half. The final result will come from a mass of accumulated operating data just as in the past for the final solution the twenty-year old problem of a grounded-neutral system came not from brilliant mathematics or special studies, but from the final check and the actual operating procedure of a great number of operating systems.

F. G. Baum: If you will read the TRANSACTIONS of the Institute of twenty years ago you will find that the problem of stability was then one of very great importance and a great deal of work was done on it at that time. The reason for its importance was this. The Stanley Company made for operation on the first long transmission systems an inductor type of generator which had no revolving coils of any kind. The generator had 100 per cent reactance. It was good for the conditions which then existed, since we had only air switches with which to open the circuit. If there was a short circuit, the voltage dropped to zero and you could open the circuit with the air switches.

Generators were actually advertised as being capable of being short-circuited without damage and only a few years ago many engineers were specifying that the short-circuit current should not be over so many times normal current.

We are now talking transmission-line stability again, and the generators are the main element in it. The transmission line will take care of itself if you will take care of the generators. The reason we are talking so much about instability is because we have flashovers, or expect them, and therefore want to be ready to take up and quickly replace the difficulty caused by the flashover. In other words, the trouble now is with flashovers, while twenty-five years ago it was that we didn't have any switches. At the time the Stanley generator was put out I was in charge of the operation of the Pacific Gas and Electric Company in which we had a number of these generators and the regulation was very poor. The voltage variation under normal operations was so bad that we couldn't operate lights at the same time as motors. Something had to be done so we applied to all the synchronous apparatus an excitation in proportion to the load. All the d-c. load current was taken around the exciters and the voltages built on the d-c. exciter in proportion to the load.

At that time I also worked out a regulating scheme for the a-c. generators which would build up the generator voltage in proportion to the drop in voltage due to the load, which as you know is practically $I \sin \theta$. I wasn't popular for proposing that because the generators were being sold because they had poor regulation, and I proposed to make them good.

For the last year and a half we have been making quite elaborate tests on power limits of transmission systems, and I agree with Mr. Wood that it is power limits and not instability which we are talking about. We don't get instability unless we have troubles outside of those that are expected and most of those come from flashovers. Stop flashovers and you won't get the instability.

The tests made have checked calculations very, very accurately. Early last spring we calculated the power limit on the Pit River System as 185,000 kw., using a power-angle diagram, which you will find in the *Electrical World* in 1902. The limit of the Edison system under actual operation has been found to be 183,000 kw. and if you will allow for the increased length of line and decreased frequency the results check.

I want to express surprise at the suggestion made in the Doherty-Dewey paper for the use of series capacity in the transmission line. You can do that in a radio system but to consider it seriously for a transmission line seems unreasonable.

The most important part of the transmission system today is the oil switch and relays. If we didn't have them today we couldn't operate our transmission systems. Any electric power system of high or low voltage and without proper relays, switches, and fuses to eliminate defective line sections is inoperative. I think you will agree with that, so I say work on the oil switches and relays. First work on the flashovers, and get rid of those so the switches won't have any more to do than necessary. Then when you get through with that, static stability will be the criterion of your power line and not transient stability.

A statement has been made with reference to the limitations of long-distance power transmission, which was quoted in a morning paper. The statement was that with the present

apparatus (and present state of mind, especially) 300-mi. transmission is questionable of economic results.

I challenge that statement. I think it should never have been made. Any man who sets a limit at the present time on power transmission either does not understand the problem or perhaps he is purposely making the statement for some other reason.

I wrote a paper for this meeting which I didn't submit because certain developments afterward made it advisable to add other information. The first sentence reads: "The natural and approximately the economic load per circuit for load transmission is given by the equation $P = 2.5\ E^2$."

If 220 kv. will not do the work, we can go to 330 kv., or some other reasonable voltage, and if 330 kv. won't do it, we can go to 440 kv. When I say that I am saying it in view of the intense study made in the last two years on insulation, coupled with the results obtained on the present system of the Pacific Gas & Electric Company, operated at 220,000 volts. It is the most successful piece of work we have undertaken, and the power is transmitted about 300 mi.

To have a real natural transmission system, you must balance the magnetic energy all along the line with the electrostatic energy. To develop that you get this equation, $I = E\sqrt{\frac{C}{L}}$. I want to call your attention to the importance of this equation. I think that equation is more important than Ohm's law or any other in electrical engineering. It is a fundamental equation. Nature tries to transmit power with the conditions given by that equation.

Now, if I want more current, I can do three things: raise the voltage, lower the reactance, or increase capacity. Most people will recognize that if you lower the reactance you will immediately get increased line capacity, but they do not appear to recognize that if you increase C you get the same results practically. I can reduce L to one-half and multiply the amount of power by $\sqrt{2}$; I can change C by doubling its value and also increase the power by $\sqrt{2}$.

Regarding line insulation, with the study we have been making in the last year and a half, I am satisfied that when we want the 330 kv. we can get it. We started this work early in 1924, not because of any troubles on our present 220-kv. transmission lines, but because we didn't want to be caught like we were in 1912 when we put in the 110-kv. lines, and later found troubles we didn't know anything about. We decided in 1924 that we would make a thorough study of insulation. The Westinghouse Company has supported that work on insulation, and the Pacific Gas and Electric Company is cooperating in the long-line tests and the practical tests which we find necessary.

So the first thing was to decide how to get at the matter of the mechanism of flashovers. I decided, after several years of study, taking probably thousands of flashovers and arriving at no mental picture of what was happening, that we had to get a reliable picture of what actually was happening whenever we had a breakdown. To get that we decided that we should probably have to get at it from a d-c. standpoint, projecting the electrons through the air, and if possible taking their pictures on the way. They are fast-moving and don't pose very long.

The pictures we have taken will, I believe, give a mental picture of the insulation of the air such as we have not had, and I believe the work done and being done will tell us the true story of line insulation.

R. E. Doherty: The extensive discussion indicates a keen interest in this important subject, and serves the very helpful purpose of focusing attention on those points which have not yet been generally agreed upon. The more they are discussed, the more they will be studied and the sooner will the various interested engineers agree upon the more important details. While perhaps there is not at this time *universal* agreement upon even the more fundamental aspects of the problem, there has been, I think, for the past two years general agreement on these fundamental aspects by those who have given the matter serious study. As I mentioned at the Midwinter Convention at Philadelphia, in 1924, the fundamental theory underlying the problem, and the equations arrived therefrom, are used by all informed engineers. Divergence of views enters only when assumptions are made regarding numerical values for a particular case. More specifically, disagreement centers, not about the transmission-line theory or the general equations of the system, but about faulty understanding regarding internal characteristics and constants of synchronous machines. Although different views regarding such machine characteristics apparently result in different estimates of maximum power which can be transmitted over a given system, I am not sure that this difference is as great as might be expected from the tone of the discussion. Messrs. Fortescue and Evans say that the calculated values in our paper are too low, but they do not indicate what these values should be. And I believe that in any definite proposed undertaking, their conclusions as to the practical feasibility of carrying out the given proposal would not be significantly different from ours. Indeed, in more recent proposals where such parallel studies have been made, the conclusions have not been widely different. All of this indicates, of course, that the protracted discussion regarding certain alleged weird behavior of synchronous machines is somewhat of a trifling character, and not of the importance which engineers not familiar with such details might be led to suspect.

I shall attempt to answer the questions raised regarding our paper, although most of them could have been answered by referring to statements in the paper. Mr. Thomas believes that it is not likely that the charging current of a long line will be a detriment under practical operating conditions. It may, indeed, be a great advantage provided the generating capacity at the end of the line is sufficiently large, as clearly shown in Fig. 2. But this is not a matter of opinion; the extent of its effect can be easily computed for any given case. It must not be concluded just because calculations made on the basis of constant terminal voltage show a larger power limit with the normal line capacitance than without it, that the same result would obtain with synchronous apparatus of a kv-a. capacity comparable with the load to be transmitted.

Mr. Griscom states that he does not understand why synchronous apparatus becomes inherently more powerful during transients. The reason is that, for the moment, the *transient* reactance, instead of the *synchronous* reactance, determines the power characteristic of the synchronous machines. The ratio of synchronous reactance to transient reactance in ordinary commercial synchronous machines is of the order of 5 to 1. It may be as low as 3 to 1, or as high as 10 to 1. In other words, in rough values the synchronous reactance is about 100 per cent, and the transient reactance about 20 per cent. Thus the machine in such a transient state is decisively stiffened up. Mr. Griscom's question would probably be removed by reading over the paper—under the heading "Transients."

He also questions whether the slope of the voltage-power curve determines the degree of stability. If the slope is zero at all values of power, it merely indicates that the voltage of the bus under consideration is not affected by any power change whatsoever, regardless of whether the synchronous machines constituting the infinite bus are of zero inertia or infinite inertia or any value between these extremes. Mr. Griscom's statement is correct that when $\frac{d\,E}{d\,P}$ approaches infinity, $\frac{d\,P}{d\,T}$ approaches O, but this is not, as Mr. Griscom states, because $\frac{d\,P}{d\,\Theta}$ is lim-

ited by the mass of the synchronous machines, but because at that moment the electrical characteristics are such that the power is not changing, although the angle Θ may be changing.

I wish to add a word about this 183,000-kw. story as related by both Mr. Evans and Mr. Baum, and which Mr. Dewey has answered. As the engineers of the country are eagerly waiting for every additional fact of operating experience bearing on this subject, it seems unfortunate, indeed, that when some real data do become available, their meaning should be so completely misunderstood or misinterpreted. When the sending end wattmeter reads 183,000 kw. and the receiving-end meter reads 135,000 kw., should we say or imply that 183,000 kw. is *transmitted over* the line? And I think that neither Mr. Evans nor Mr. Baum would, after serious thought, adduce that test (which our calculations check) as evidence that our calculated values are much too low. In Mr. Evans' published work, he calculates, as most every one does, the receiver-end, not the sending-end, power.

Mr. Evans raises two other points: One is that the maximum power can be increased by reducing the reactance of the generator; the other, that Fig. 2 might be misleading. As to the one, the authors heartily agree, as presumably every one else does. Nobody would question that. The question is *how* will you decrease the reactance. Mr. Evans is referred back to the paper to the heading "Design," where this matter is fully discussed. The generator capacities given are based on present-day practise —synchronous reactance approximately 100 per cent. Nothing would be gained by cutting the ratings to, say, one-half, thus reducing the per cent reactance to 50 per cent. That would not increase the maximum power. The question is how would one alter the design of a machine of given magnetic dimensions in order to lower the synchronous reactance, and to what extent could it be thus lowered. There could not be much disagreement among informed designing engineers on that point. After that is done, any further reduction must be obtained by increasing the active volume of the machine, or by adding more machines. Thus, as Mr. Evans says, and as the paper clearly points out, "quite marked increases in the stability" can be obtained in these ways, but there are perfectly obvious reasons, as the paper also points out, why this process cannot be extended far enough to satisfactorily solve the problem.

The other point raised by Mr. Evans is well founded. The authors acknowledge that the title of Fig. 2 should be more specific, and will revise it accordingly. The illustration refers to a 250-mi. straight-away line with synchronous-motor load.

Mr. Fortescue does not know of "a single case in which a system was thrown out of step by a sudden increase in load, or short circuit due to low excitation." There have been such cases, nevertheless. The September 1919 trouble of the Commonwealth Edison Company, described by Dr. Steinmetz in the 1920 TRANSACTIONS, is one notable example among others.

The authors naturally agree that if an additional line with duplicate sending and receiving apparatus be installed, the maximum power will be increased. Two power *systems* will obviously carry more than one. But that is not the point. Fig. 2 merely shows the relation between generating capacity, number of lines, and maximum power. To say, as Mr. Fortescue does, that two "properly designed" systems with "proper size generating stations," etc., etc., will always carry more than one, would hardly bear close scrutiny where costs are regarded, because "proper size" for maximum power may be prohibitive in cost.

It does not require a mechanical model to prove the platitude that if "the terminal voltages are kept constant," the power limit will be the limit of the line itself. But to the authors' knowledge the "perfect regulator" to hold this condition does not exist. When it shall exist, or else when some other method than synchronous operation is utilized, it will be time enough to talk seriously about the limit of the line alone. I have discussed this problem of regulation in my comments on Mr. Fortescue's paper.

Mr. Fortescue also bespeaks the gain from changing the generator characteristics. Such changed generators, he avers, will permit of operation with a "high stability limit," but he doesn't say how high. And the whole point, if there is any, depends upon *how high*. He, like Mr. Evans, is referred to the paper under the heading "Design."

They also mention that the authors have not discussed the effect of load characteristics. Loads which are functions of the voltage, such as lights and certain classes of converters feeding a constant voltage d-c. bus, are inherently stable. These have a maximum power, but that is not the limit of stability. Indeed, there is no stability limit with a plain impedance load. The shaft load of induction and synchronous motors is independent of voltage, and for these, the maximum power limit and stability limit coincide. Thus, a composite load would have greater stability than a pure shaft load of the same amount.

H. H. Dewey: In closing, I shall take up some of the points that have been brought up in the discussion of the paper by Mr. Doherty and myself.

Mr. Thomas in his discussion brought out a point in regard to the relation of the cost of the terminal apparatus to the cost of the line, pointing out that the line cost was very high per kilowatt. It might run to $125.00 per kilowatt, whereas the terminal apparatus, generators and motors, would be very much less than that, perhaps $8.00 or $10.00 per kilowatt, and that since the terminal apparatus was an important factor in the power limit of the completed system, the place to work to extend our power limits was on the synchronous apparatus. I agree with that thoroughly, and we can do considerable along that line.

Mr. Evans and Mr. Fortescue spoke of the possibilities of synchronous-apparatus improvement as a thing about which we were unduly pessimistic in our paper, that is, the question of what could be done to increase the power limit of terminal apparatus. Our paper did not stress that point for the reason that it seemed obvious. In presenting the curve given, showing the breakdown of a given generator and a given motor, it is quite apparent that the power limit is determined by the size of the generator. If we had a generator of double the size, or a motor of double the size, we would get double the power. In line with Mr. Thomas' suggestion then, since we can put on generating apparatus for $8.00 or $10.00 per kilowatt, we can obviously increase the size of the generator until we strike an economic balance between the size of the generator and the capacity of the line.

Now, the size of a generator is determined by its characteristics. We would fool ourselves if we tried to take a 10,000-kilowatt generator and cut its reactance in half, change its field, style, etc., and still call it a 10,000-kilowatt generator. It wouldn't be a ten-thousand any more; it would be fifteen or twenty, and it would cost more money to build it. That is an obvious thing that we did not stress in our paper. Since generating and receiving apparatus is a large factor in limiting the power that can be transmitted over a system, everything possible should undoubtedly be done to improve their characteristics.

The paper tried to cover the essential points in determining what a given set-up would give. There was a point that Mr. Evans brought up and Mr. Fortescue also, in their discussion, in regard to the effect of charging current of transmission lines. They took issue with Mr. Doherty and myself in stating that charging current was an actual detriment. They evidently did not read our discussion of that point very carefully.

With given apparatus, with a given generator, with a given receiving-motor load, and a given voltage at each end of the line, which we always have, charging current *is* an absolute detriment. We reduce the amount of power which can actually be transferred from the generator to the receiver end, no matter what the relation of charging current of the line to the generator. The charging current of the line on a high-voltage system will actually reduce the amount of power you can transfer from the generators

to the motors, because it reduces the excitation of the generators and motors.

Mr. Evans brought out a point in which he indicated that our calculations on a 250-mi. line were in error in that it was considerably less than the value that had already been obtained in practise by the Southern California Edison Company. He stated that our calculations showed the limit to be 115,000 kw. whereas they obtained 183,000 kw. The calculation is 120,000 kw., not 115,000 as read from the curve by Mr. Evans. We have made a calculation of the Southern California Edison System based upon data furnished by Mr. Barre which showed 183,000 kw. Our check calculations, made in the same manner as our calculations in the paper, came within 5 per cent or thereabouts of the same results.

The big difference in these values comes in this respect: The 120,000 kw. shown in the paper was receiving load. The 183,000 kw. obtained in actual practise on the Southern California Edison Company's system was at the generating end. At the time they had 183,000 kw. input they had 135,000 kw. output. Thus, we have an error of only 120,000 kw. to 135,000 kw. and there is a difference of 20 per cent in frequency, that is, 50 instead of 60 cycles, which brings it to almost exactly the same thing.

Mr. Wood spoke of the term that has been quite often used to describe "power limit," that is, "instability," and sounded a warning against its use. I agree with him thoroughly on that. It was for that reason that the title of our paper was made Power Limit. Power limit is something that is perfectly harmless, and I agree that the use of the word instability is likely to cause concern where concern is not necessary.

Mr. Fortescue's discussion was quite lengthy and very helpful. He took issue with some parts of our paper. Some of these points I did not quite digest. Some of them made me rather think that he was saying the same thing we were saying only in different words, particularly as he laid very great stress on the effect of voltage regulators. I agree with him thoroughly that the regulator is a very important thing, and is so much more important than we originally thought that it makes a great deal of difference in the ultimate capacity of the transmission system.

We have very few real things to worry about. I agree with Mr. Wilkins that the final solution of this problem is going to come in the data that we get from actual operation, but so far the data of actual operation, where we have been able to obtain data, have checked so closely with our present methods of calculation that we feel we are in a position where it will be possible to predict what will happen to any given system. The more complicated the system, the more difficult it is to calculate, and when we get such complications, we must resort to some scheme such as Mr. Nickle has described[9], just as we reach the limit of the possibility of calculating short-circuit current on a network such as described by Mr. Wilkins with 880,000 kw. of generating capacity and thousands of miles of interconnected transmission line. That would be a hopeless case to calculate the short-circuit current, but we have calculating machines that arrive at these values very closely. We can likewise use the Nickle calculator or some other device to arrive at our stability problem. We are not worrying about the question of stability or power limits; we know pretty closely how to calculate them, and it is very essential that we do so, as the amount of power that can be carried over a given line greatly influences the cost of delivered power.

9. "Oscillographic Solution of Electromechanical Systems," by C. A. Nickle, Jour. A. I. E. E., December 1925, p. 1277.

C. L. Fortescue: In regard to Mr. Thomas' discussion, he emphasizes the effect of damping factors. In our calculations we try to work in the effect of the damping factor as much as possible, but Mr. Thomas remarks that if you increase the damping factor sufficiently the machine will be critically damped. We know that in practise this condition is never met. We have records of power swings and they are as far as we know never critically damped.

As regards Mr. Doherty's discussion I think we are substantially in agreement. I think an explanation of the differences in view might be somewhat as follows:

Two investigators have approached this problem from somewhat different angles, and while there is no disagreement in the fundamentals of the problem, there is a little apparent disagreement in what might be termed derived ideas.

The problem of stability involves so many factors, the speed of the exciters, the speed of the regulators, the inherent tendency of the machines to correct themselves, etc., that it is quite excusable that there should be a slight difference of opinion.

Now, I think you might say that Messrs. Doherty and Dewey and myself agree on what should be. We probably agree pretty well on what actually is, but we disagree somewhat in regard to what may be or might be, Messrs. Dewey and Doherty putting the "might be" a little closer to the "is," and I myself putting the "might be" a little closer to the "should be."

I hope that the result of our investigations will finally bring us both to an agreement on the "might be" and that the "might be" will finally come closer to the "should be" than Messrs. Doherty and Dewey place it at present. That is my hope. I am quite open-minded about this.

The final decision about this particular question will undoubtedly come about from actual work in the field and in the laboratory. We shall, of course, make calculations and analyze these results and there is no doubt at all that we shall finally come to a substantial agreement. In that day I hope we will be very close to the "should be."

Application of Electric Propulsion to Double-Ended Ferry-Boats

BY A. KENNEDY, Jr.[1] and FRANK V. SMITH[1]

Associate, A. I. E. E. Non-Member

Synopsis.—*The double-ended ferry-boat propelled by means of a bow and stern propeller has become the recognized standard type, due to its maneuvering possibilities and general handiness in congested harbors.*

In all cases in which the prime mover is directly coupled to the two propeller shafts which must necessarily turn at the same revolutions per minute, the over-all propulsive efficiency is lowered due to the performance of the bow propeller.

The electric drive system permits of applying power when and where required and to any degree desired. Tests on the double-ended ferry-boat, W. R. HEARST, show a material gain in propulsive efficiency when driving the bow propeller electrically at a speed which gives neutral thrust. Later tests indicate, however, that there is no substantial difference in the propulsive efficiency whether the bow propeller is driven electrically at neutral thrust or is electrically disconnected and driven by the water. Sufficient tests have not been made, however, to show that this is true in all cases.

The reciprocating steam-engine or Diesel-engine type of drive, in which both shafts are direct connected, requires approximately 19 per cent more horse power at the propeller shafts than the electric system, due to the difference in propulsive efficiency.

The calculated fuel consumption of a typical reciprocating steam-engine drive with the direct-connected system shows that it requires approximately 40 per cent more fuel than the steam turbine electric system, due to the difference in propulsive and thermal efficiencies.

The electrical transmission losses are less than the propulsive efficiency losses of the direct systems. In addition to the more efficient method of power application, electric drive also has many inherent advantages, such as rapid maneuvering qualities and ease of control.

The Ward Leonard system, similar to that used on the Chicago fire boats which were put in operation in 1908, permits of the use of pilot-house control, eliminating the personal factor which is always present with the engine-room telegraph.

The operating records of ferry-boats in service prove electric drive to be reliable.

The respective field of application of turbine electric drive or Diesel electric drive for double-ended ferry-boats depends upon the relationship of first cost to the operating changes and needs of the service.

THE double-ended ferry-boat presents a problem unique in marine and electrical engineering and the data pertaining to the specific applications which follow bring out quite forcibly the manner in which electric drive overcomes the inherent losses of other systems and brings about a higher over-all efficiency than formerly attained in preceding types.

Briefly, the economic gains brought about through the electrification of the main propelling machinery consist of two things:

I. Gain in propulsive efficiency due to the method in which the power is applied to the forward and aft propellers.

II. Gain due to the higher thermal efficiency of the turbo electric and Diesel electric machinery as compared to the reciprocating steam engine.

It has long been recognized by naval architects and marine engineers that an inherent loss in propulsive efficiency exists when one prime mover is directly coupled to a bow and stern propeller, which must necessarily turn at the same rev. per min.

Compromise designs have been made in an attempt to decrease the bow propeller losses, but it is not apparent from published test records that this has resulted in an increased overall propulsive efficiency.

Several tests have been made on reciprocating steam engine-driven, double-ended ferry-boats, driving with the stern screw with bow screw removed, pulling with bow screw with stern screw removed, and driving with both screws at the same rev. per min. A comparison of the power input required to give the same boat speed with the various systems is given in Table VI.

Driving with the stern screw with forward screw removed consumes the least power at a given speed. Due, however, to the fact that ferry-boats operate in congested waters and usually on short trips, it is not practical to turn the boats around, and therefore the double-ended arrangement has come into use as being the most practical for this type of service. The double-ended ferry-boat may, therefore, be considered a compromise type, in which high propulsive efficiency is sacrificed for maneuvering ability and general handiness.

As electric power may be applied when and where required and in any degree desired, it is but natural that this type of propulsion finds a ready application in the double-ended type of ferry-boat, as the two propellers may be driven at such relative speeds that the entire work of propulsion is accomplished entirely with the after screw.

The general method adopted in the various electrically driven ferry-boats is the driving of the boat with the after screw and the operation of the bow screw at sufficient rev. per min. to overcome either a pulling or pushing affect.

Tests have been made on the electrically driven ferry-boats and the power input to the bow screw at neutral thrust noted. The results may, therefore, be compared

1. Both of the Marine Engineering Dept., General Electric Co., Schenectady, N. Y.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

with the tests previously made on the reciprocating steam-engined ferry-boats.

The electric system is comparable to the one screw arrangement plus the additional power required to drive the bow screw.

As will be shown later by records of tests, the increased power required by the two-screw arrangement, driving at the same rev. per min., is approximately 25 per cent as compared to driving with one screw, whereas with the electric drive, the bow screw may be operated at neutral thrust with an expenditure of power amounting to approximately five per cent.

The data which follows include a description of the electric equipment, control features, and various tests on the following electrically driven boats:—a-c. turbine electrically driven ferry-boats—*W. R. Hearst*, *Rodman Wanamaker* and *Geo. W. Loft*; d-c. Diesel electrically driven ferry boats—*Golden Gate* and *Golden West*; and d-c. turbine electrically driven ferry boats—*Hayward* and *San Leandro*.

The *W. R. Hearst*, *Rodman Wanamaker*, and *George W. Loft* are operated in New York harbor by the City of New York and were placed in service during 1923 and 1924.

The propelling machinery consists of an 8-stage horizontal Curtis steam turbine, direct-connected to an a-c. generator. This generator furnishes power to two double squirrel-cage induction motors, each rated 36/52 poles, 2100/100 h. p., 176/122 rev. per min. The 36-pole winding is used to drive the boat by means of the aft propeller, and the 52-pole winding to drive the forward propeller at or near neutral thrust. The rotor of one motor is direct-coupled to the forward propeller shaft, and the rotor of the other motor is direct-coupled to the aft propeller shaft.

Excitation and power for the electrically-driven auxiliaries, lighting, etc., is obtained from one 125-kw., 220/110-volt, d-c. generator, which is driven by a geared Curtis condensing steam turbine. There is a second set, of the same capacity, which is a spare. Practically all continuous duty auxiliaries excepting the boiler feed pump are motor driven.

The control station is located in the engine room. The operator normally controls the ship by means of an electric lever and a speed switch. Emergency levers are provided so that in case of the failure of electric control or the turbine variable speed maneuvering governor, the propelling machinery may be operated by the manually operated levers.

The electric lever controls the solenoid operated contactors and the speed switch controls the governor setting of the turbine.

Due to the exacting maneuvering requirements met on ferry-boat service, the 36-pole induction motor winding was designed to give normal full load torque with super-excitation of the generator field, irrespective of the turbine revolutions per minute or generator frequency. This was accomplished by using a double squirrel-cage rotor winding. This winding consists of a winding having a relatively high resistance and low inductance, electrically, in parallel with a winding of relatively high inductance and low resistance. When starting, the reactance of the low resistance squirrel-cage is high, which causes the current to flow chiefly through the high resistance winding.

At full speed or when the motor has pulled in step, the reactance of the low resistance winding is low and the current flows chiefly through this winding. This permits a relatively high torque at starting and an efficient motor when running in step.

The advantage of this type of motor is that it eliminates brushes, collectors, external resistors, and short-circuiting contactors. It is possible to maneuver without slowing down the turbine or generator revolutions, but if this is done, it requires a longer time for the motor to be pulled into step than if the turbine revolutions are reduced.

On July 28, 1923, several reversal tests were made and it was found that with the boat going full speed ahead, the propeller could be stopped in about five seconds from the time the signal was given from the pilot house, reversed and pulled into step in the opposite direction in about ten seconds, and the boat stopped dead in the water in from fifty to sixty seconds. These tests were conducted in New York harbor, and therefore, it was impossible to note the boat's speed and difficult to determine when the boat had come to rest in the water. These readings are therefore mentioned as being approximate and only of general interest.

Before starting tests on the propelling machinery the bow motor was electrically disconnected and readings taken of the stern and bow motor rev. per min. We were unable to estimate the speed of the boat. These readings give the relative rev. per min. of the stern and bow motor when the ship is being propelled by the stern motor, the bow motor being driven by the propeller. When the stern propeller was being driven at 171 rev. per min. the bow propeller drove the bow motor at 100 rev. per min. During and following these tests, the end play of the bow motor was noted. When power was applied, the bow motor end play was taken up in a forward direction, occasionally coming aft due to waves, etc. It is believed, therefore, that approximately neutral thrust or a slight pull was exerted when the bow motor was driven electrically.

During the tests on the propelling machinery the following readings were taken:

TABLE I

W. R. Hearst

A-C. Generator				Aft Motor		Forward Motor	
Line Volts	R.P.M.	Field Amps.	Field Volts	Amps.	R.P.M.	Amps.	R.P.M.
2500	3050	135	110	515	165	39	118
2275	3000	125	110	560	167	39	118
2300	3050	125	110	550	168	50	118
2350	3000	130	110	530	165	40	118
2350	2900	130	110	500	158	35	112

Based on factory tests, the calculated power delivered to the bow and stern propeller shafts is as follows:

TABLE II

Kv-a.	P.F.	Eff.	Kw. Input	Kw. Output
Aft Motor				
2230	74	94	1650	1550
2207	76	94	1675	1575
2190	76	94	1660	1560
2160	75	94	1620	1525
2036	73.5	93.9	1495	1405
Forward Motor				
169	53	83.5	90	75
153.5	57	84.5	87.5	74
199	64	84.0	127	107
162	57	84.3	92.5	78
143	49	82	70	57.5

The calculated cable loss between the generator and the propelling motors is approximately 1700 watts with full load on the bow and stern motor windings. The combined bow and stern motor full load efficiency is 93.7 per cent at 74.8 per cent power factor. From the results of these tests it appears that when the stern motor was delivering 2100 h. p., the bow motor was delivering approximately 107 h. p., or 5.13 per cent of the power delivered by the stern motor.

Test results check the estimates made by M. G. Kindlund, Naval Architect, based on model tests, as well as general estimates made by Commander S. M. Robinson, published in the December 1920, *Marine Engineering*.

The propellers on the *George W. Loft* were of a different design, giving a different relationship of the bow and stern revolutions per minute for neutral thrust. Based on these tests and tests conducted on other electrically driven ferry-boats, it was decided that it is practically as efficient to drive the bow motor by means of the bow propeller as it is to drive the bow motor electrically; that is, instead of having an output of the stern motor of 2100 h. p. and of the bow motor of 107 h. p., practically the same results can be obtained by using the same generator output on the stern propeller motor, which would be equivalent to slightly more than 2207 h. p. output of the stern motor, due to the difference in efficiencies, allowing the water to drive the bow propeller. This permits the use of a single speed motor instead of a double speed motor.

The *Golden Gate* was the first Diesel electric, double-ended ferry-boat to be placed in service and is therefore taken as an example of Diesel electric drive. This boat was placed in service in San Francisco Bay, July 4, 1922.

The electric propelling machinery consists of two Diesel driven, direct-current, separately excited generators, each rated 360 kw., 250 volts, 225 r. p. m., and two 35-kw., 115-volt exciters, each mounted on the shaft extension of the main generators. The generators are normally electrically connected in series. There are two separately excited propelling motors each rated 750 h. p., 145/180 r. p. m. The rotor of one motor is direct-coupled to the forward propeller shaft, and the rotor of the other motor is direct coupled to the after propeller shaft. Either one of the two exciters is used for exciting the generators, propelling motors, control, and furnishing power for the electrically driven auxiliaries, lighting, etc.

The control is of the Ward Leonard or voltage-current system, similar to that first used on the Chicago Fire Boats, *Joseph Medill* and *Graeme Stewart*.

The direction of rotation and rev. per min. of the propelling motors is controlled by varying the excitation of the generator fields and the relative rev. per min. of the bow and stern motor by changing the field excitation of the motors. It is possible, with this type of control, to change the relative bow and stern propeller rev. per min. at any predetermined position of the controller.

There are three control stations, one in each pilot house and the third station located in the engine room.

Normally, the generators are electrically-connected in series but cut-out switches are provided so that either generator may be disconnected, the boat being operated by the remaining unit. The motor field control permits utilizing full output of one engine, which corresponds to approximately 80 per cent propeller rev. per min.

The several severe tests, and also the operating records in normal service, have demonstrated the advantage of pilot house control as well as the reliability of this type of machinery.

This ferry-boat has been stopped from full speed ahead to dead in the water in 30 to 35 seconds.

More complete tests were conducted on the *Golden West*, which is a sister ship of the *Golden Gate* and has the same propelling equipment. We shall, therefore, use results of the tests conducted on the *M. S. Golden West*.

The following readings were taken April 6, 1923, when running over the measured mile off California City:

GOLDEN WEST

TABLE IV
FORWARD MOTOR ELECTRICALLY DISCONNECTED

	Aft Motor			Foward Motor		
Run	Amperes	Volts	R.P.M.	Amperes	Volts	R.P.M.
7	975	480	170.6	0	0	123.7
8	975	475	171	0	0	124
9	1000	475	170	0	0	126
10	1000	475	170	0	0	125
11	980	475	170	0	0	.126
12	960	475	170	0	0	126

Based on factory tests, the power delivered to the bow and stern propeller shaft is as follows:

TABLE V

	Aft Motor		Forward Motor		TotalMotor
Run	Kw. Input	Kw. Output	Kw. Input	Kw. Output	Excit. Kw.
1	540	507	28.2	22.5	14.
2	485	457	41.3	35.5	14.1
3	537	505	36	30.2	14.3
4	472	445	61.2	55.1	13.9
5	718	672	27.1	21.4	11.9
6	661	620	50.2	44.3	11.3

Results of these tests show that the average power output of the bow propeller motor was 6.8 per cent of the stern motor. The full load overall efficiency, including generator losses, exciter losses, motor losses, cable losses, and rheostat losses, when the stern motor is delivering 750 h. p. and the bow motor 51 h. p., is 83.9 per cent.

Unfortunately, there is no notation on the tests conducted that the bow motor was exerting neutral thrust or a forward pull, but based on the relative rev. per min. of the stern and bow motor when the bow motor was being driven by the water and when the bow motor was electrically driven, we believe that there was a slight forward pull, which may or may not account for the slightly higher power input to the bow motor than that shown on the tests conducted on the *W. R. Hearst*.

The *Hayward* and *San Leandro*, which were placed in service on San Francisco Bay in 1923, are of the d-c. turbo electric type.

The electric propelling machinery consists of a 1100-kw., 3600-rev. per min., horizontal, Curtis steam turbine direct-connected through a reduction gear to a 1000-kw., 900-rev. per min., separately excited generator. Mounted on the shaft of the main generator is a 75-kw., 115-volt exciter. The 1000-kw. generator supplies power to two separately excited, double armature motors, each rated 1200 h. p., 100 to 125 rev. per min. The armatures of one motor are direct-coupled to the forward propeller shaft and those of the other motor to the aft propeller shaft.

The 75-kw. generator supplies power for exciting the 1000-kw. generator, the two propelling motors, control, auxiliary power, and lighting.

The control station is located in the engine room, and the control is of the Ward Leonard or voltage-control system, similar to that described for the Golden Gate ferry boat.

The above boats have been in continuous operation since their inauguration into service. As an example of the severe duty required of these boats, the following data, covering a short period of their operation, are given.

Between May 31, 1923 and February 10, 1924 the *Hayward* made 10,500 trips, traveled 30,312, miles and carried upwards of 4,000,000 passengers. The two boats, in a year's time, carry upwards of 10,000,000 people and the largest number of people carried in one day by one boat has aggregated upwards of 30,000 people. They serve one of the most congested terminal traffic lanes in the world. Six hundred and fifty electric trains per day serve the traffic at the Oakland Terminal and during the one hour rush period between five and six o'clock in the evening, 48 trains are moved.

The operating record of these boats is given rather than a repetition of test data on the previous boats, due to the fact that it brings out one very essential point, that is, the absolute reliability of this type of machinery where continuity of service is the paramount factor.

Comparative Efficiencies

The following section is devoted to an analysis and economic comparison of the reciprocating steam engine driven and turbo electric driven types of ferry-boats.

This will tend to show in a concrete way the fundamental differences that exist due to both the propulsive and thermal factors.

The Diesel electric system has the same advantage as the turbo electric drive in the matter of gain due to the difference in propulsion characteristics. The high thermal efficiency of Diesel engines, as compared to either the reciprocating steam engine or turbo electric, is fully recognized, but due to the fact that this subject has been so fully covered by the Diesel engineers, it is omitted from this paper.

The selection of steam turbines or Diesel engines depends upon the relationship of first cost to operating costs and the needs and requirements of the service, and is also influenced, to a more or less extent, by the past experience of the operating companies.

Relative Power Requirements. The relative power required to maintain a given boat speed, as ascertained by tests made on the reciprocating steam engine driven type of double-ended ferry-boats, is given in Table VI.

Conclusions to be Drawn from Tests

A. Propelling with bow screw, stern screw removed: The tests show that over 50 per cent more power is required when pulling with the bow screw than when pushing with the stern screw.

B. Pushing with stern screw, bow screw removed: This method takes the least power and may, therefore, be considered the base with which to compare other

systems. In service, however, this system is not practical.

C. Driving with bow and stern screw at same rev. per min.: The tests disclosed that approximately 25 per cent more power is required to maintain the same speed of boat than in system "B". This is the usual method of propelling a double-ended ferry-boat in which the prime mover is directly connected to the two propeller shafts.

D. Driving with after screw only, bow screw operated to give neutral thrust; electric drive system only: The series of tests conducted on the electrically driven ferry-boats disclose the fact that the bow propeller may be operated to give neutral thrust with an expenditure of power amounting to approximately five per cent of the total.

In service, we are interested only in systems "C" and "D". As the relation between these two systems is of the order of 125 per cent to 105 per cent, taking the electric drive system as the base, the new relation becomes 119 per cent and 100 per cent, respectively.

In other words, the electric drive system requires but 84 per cent as much power as the reciprocating engine drive to attain the same boat speed, due to the gain in propulsive efficiency.

Analysis of Steam and Fuel Consumption

The 2200-s. h. p. turbine electric, a-c. driven ferry-boat has been selected to compare with a reciprocating, steam engine driven ferry-boat as water rate and efficiency tests were conducted at the factory on the electrical equipment. The s. h. p. required by the reciprocating engine driven type to be comparable will be 2620. On account of the long line shafting required in the latter type, a mechanical efficiency of 90 per cent is assumed, which gives an i. h. p. of 2910.

Comparative Water Rates of Main Propelling Machinery:

a. Reciprocating steam engine; so far as the authors are aware, there have been no data published regarding water rate tests of reciprocating steam engines installed on ferry-boats in which either the power developed or steam conditions are comparable to the turbine electric installations. Recourse, therefore, must be made to such formulas as Jenson's or the later methods deduced by E. A. Stevens, Jr.

Average values range from 14 to 17 lb. per i. h. p-hr. for saturated steam at 250-lb. gage pressure, and correcting for 200 deg. fahr. superheat, these values are reduced to 11.5 to 14 lb. per i. h. p-hr.

In the comparisons which follow the minimum value of 11.5 lb. per i. h. p-hr. is used.

b. The water rates of the turbo electric equipments furnished for the New York municipal ferries were determined by a very rigorous series of tests. This amounted to 10.135 lb. per s. h. p. per hr. including the generator and motor losses, with the hand valves open. Under the following steam conditions—pressure 250 lb. gage, superheat 200 deg. fahr., vacuum 28.5 in.—quite a throttling loss takes place at rated full load with

the hand valve open. With the hand valve closed, in which rated full power is available, the water rate is 9.98 lb. per propeller shaft horse-power hour. In the comparisons which follow a flat rate of 10.0 lb. is used. (The hand valve is used for overload conditions during rush hours.)

Conclusions

1. That the reciprocating steam engine or Diesel engine, in which the bow and stern propellers are operated at the same revolutions per minute, requires approximately 19 per cent more power than the electric system, due to difference in propulsive efficiency.

2. That the fuel consumption of the reciprocating steam engine drive with the direct connected bow and stern propellers requires approximately 40 per cent more fuel than the turbine electric system, due to the difference in propulsive and thermal efficiencies.

3. That the operating records of the boats in service prove electric drive to be reliable and a great step forward as a method of propulsion for the double-ended type of ferry-boat.

4. That in the comparison of turbo d-c. and a-c., the d-c. is superior in flexibility, simplicity of control, and general handiness afforded by bridge control. That the a-c., however, is slightly more economical as regards fuel consumption.

5. That both turbo electric and Diesel electric drive overcome the inherent propulsive efficiency loss of the reciprocating steam engine type of drive and that their respective spheres of application are dependent upon the relationship of first cost to operating charges and needs of the service.

Discussion

H. F. Harvey, Jr.: About the only comment which I have to offer is that sufficient emphasis has not been laid on the maneuvering feature. With direct control from each pilot house it is very evident that the one in charge can maneuver the boat more easily than by means of the ordinary signals to the engine room.

I believe that thus far most ferry-boats with electric drive are used on fairly long runs. Such runs do not show to advantage the speedier maneuvering, either when entering or leaving the slips. For short runs as between New York and Jersey City, or between Camden and Philadelphia, electric drive would show a decided advantage in this respect.

Ferry-boats are usually operated in congested waters where it is very necessary to have close control of the vessel in order to avoid accidents. Electric drive, I believe, affords quicker stopping and reversing than any other drive. Too much emphasis, therefore, cannot be placed upon the superior maneuvering qualties of electrically driven ferry-boats.

F. K. Kirsten: There has been no mention made in the paper as to the design of the propellers involved in ferry-boat propulsion. It seems that these boats are designed to travel in either direction with practically the same propeller showing. As a consequence, some design must be used on these particular ferry-boat propellers differing from that used in ordinary steamers. I would like to know if any particular statements could be made in that direction.

M. J. Whiteman: I should like to know if it is possible with a ferry-boat having four-propeller drive to rotate the boat on a center or pivot in order to make quick turns.

A. Kennedy Jr.: Mr. Whiteman asked if it is possible with an electrically-driven ferry-boat to pivot the boat in order to make quick turns, and also the number of electrically driven ferry-boats that are in operation. All electrically driven ferry-boats use the same method of steering as that used on reciprocating steam engine driven ferry-boats; that is, they use one rudder. I do not know of any way to make a ferry-boat pivot in order to make quick turns unless some change is made in the design of the boat.

At the present time there are eight electrically driven ferry-boats in operation, three in New York, four in San Francisco, and one at Poughkeepsie. These, I believe, are the only ones, but of course, others are being considered.

Professor Kirsten asked whether or not it was necessary to modify the design of the propellers for electrically driven ferry-boats. Normally, with steam engine driven ferry-boats, a compromised propeller design is used, as it is necessary to use the faces and backs of the blades. A good deal of work has been done trying to improve the over-all propulsive efficiency by decreasing the amount of power required to drive the forward propeller. As far as I know, no one has been able to improve the over-all propulsive efficiency by using this specially designed propeller, but they have reduced the power required to drive the forward propeller.

With electric drive it is possible to use a standard propeller for the simple reason that the bow propeller does not do any work. Only the face of the propeller is used for driving, whereas with the reciprocating steam engine connected to a through shaft a special design is made as the back of the blade is normally used on the forward propeller to assist in driving the ferry-boat.

Some Features and Improvements on the High-Voltage Wattmeter

BY JOSEPH S. CARROLL[1]

Associate, A. I. E. E.

THE high-voltage wattmeter herein described is the result of three years of study and experimental work carried on at Stanford University. Included in this report on the wattmeter is a description of a high-voltage voltmeter and a crest voltmeter. The operation of these instruments is entirely independent of any connection to the supply transformers. In other words the equipment in its present form can be connected directly in on the high voltage line, and simultaneous readings of the power, total effective voltage, crest factor, and line current can be taken at any instant and at any voltage up to 175 kv. to neutral.

The wattmeter consists of an ordinary low-voltage instrument located in an electrostatically shielded cage that is at high potential. The current coil of the meter is connected directly in on the line with an ammeter in series. The potential coil with its special high resistance multiplier is connected from the line to ground. There is also a milliammeter in this circuit. (See diagram of connections.) These instruments are all read with telescopes at a safe distance. This special multiplier consists of a column of ordinary tap water 16.5 ft. long and 3/16 of an in. in diameter; it has a maximum resistance of approximately three million ohms and a current carrying capacity of 65 milliamperes. A rubber air hose is used as container for this column of water. This hose is wound into a helix of five turns about one foot in diameter and the helix is placed with its axis vertical between two horizontal circular plates four feet in diameter and separated thirty inches. These plates are supported by three bakelite strips 1 in. by 3 ft. 1 in. long. The hose is held in place by means of a single bakelite strip with wooden pegs of 3/8 in. maple doweling projecting out radially, on the end of which the hose is fastened. (See Fig. 2.) The water is forced up the hose by means of a gear pump, the maximum pressure used being about 80 lbs. per sq. in. and the maximum flow being about 1.5 gal. per min. After reaching the top of the helix and passing the wattmeter connection, the water flows through about seven feet more hose and is then discharged to the ground in a spray, the spray completely breaking the circuit.

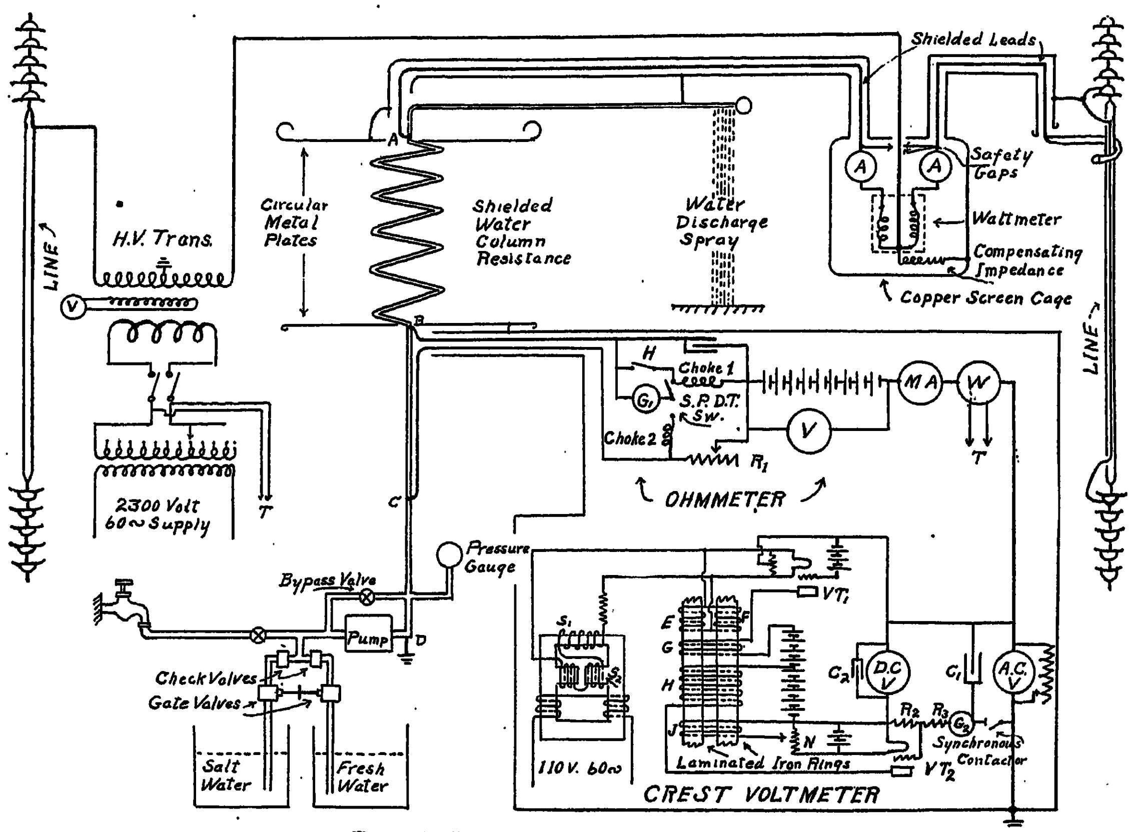

FIG. 1—WATTMETER CIRCUIT ASSEMBLY

1. Elwell Fellow in Electrical Engineering, Stanford University, Palo Alto, Calif.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., September 15-19, 1925.

When the current flows through the water resistance the water, of course, warms up, the heating being accumulative as the water moves up the hose. The effect of this is a somewhat complex change in resistance which in turn makes the voltage gradient down the column differ from a straight line function. This is a condition that must be controlled before correct electrostatic shielding can be accomplished. First of all a means must be had for keeping the voltage gradient down the column constant at all voltages. The next problem is then to match the potential of the water column at every point by the external field between the two plates.

Before going further, let us solve the problem of a current flowing through this column of water that is being constantly supplied at the lower end with cool water and wasting the warm water at the top. The resistance-temperature coefficient of ordinary tap water varies considerably for different temperatures. The

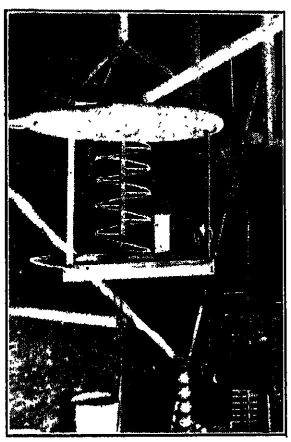

FIG. 2—THE SHIELDED WATER-COLUMN RESISTANCE USED AS THE WATTMETER MULTIPLIER

following has been found to be approximately the relation of resistance to temperature between zero and 100 deg. cent.[2]:

$$R_t = \frac{40\,R_{20}}{20 + t}$$

where R_t is the resistance at any temperature t (deg. cent.) between 0 deg. and 100 deg. and R_{20} is the resistance at 20 deg. cent.

Beginning at the ground end, the rise in temperature $d\,t$ in a differential length $d\,l$ of the column is as follows:

$$d\,t = \frac{I^2\,d\,r\,\dfrac{d\,l}{V}}{4.184\,A\,d\,l} = \frac{I^2\,d\,r}{4.184\,A\,V} \qquad (1)$$

where I = current in amperes through the w. c.

$d\,r$ = resistance of a length $d\,l$.

V = velocity of water through the column in cm. per sec.

A = area of column in sq. cms.

4.184 = mechanical equivalent of heat.

Integrating the above equation the actual temperature of this differential length is

$$t = \frac{I^2\,r}{4.184\,A\,V} + T \qquad (2)$$

T being the temperature of the water entering the column.

$$d\,r = R_t\,\frac{d\,l}{A} \qquad (3)$$

R_t specific resistance of the water at temperature t.

$$R_t = \frac{40\,R_{20}}{20 + t} \qquad (4)$$

R_{20} specific resistance at 20 deg. cent.

Substituting (4) in (3),

$$d\,r = \frac{40\,R_{20}\,d\,l}{(20 + t)\,A} \qquad (5)$$

Substituting (2) in (5),

$$d\,r = \frac{40\,R_{20}\,d\,l}{\left(20 + \dfrac{I^2\,R}{4.184\,A\,V} + A\right)A} \qquad (6)$$

Simplifying,

$$(83.68\,A\,V + 4.184\,A\,V\,T + I^2\,r)\,d\,r = 167.4\,V\,R_{20}\,d\,l \qquad (7)$$

Integrating,

$$\left(\frac{I^2\,A}{2}\right) r^2 + A\,V\,(83.7 + 4.184\,T)\,r - 167.4\,V\,R_{20}\,l = 0 \qquad (8)$$

Solving for r,

$$r = \frac{-\,A\,V\,(83.7 + 4.184\,T) \pm \sqrt{A^2\,V^2\,(83.7 + 4.184\,T)^2 + 335\,V\,R_{20}\,I^2\,l}}{I^2} \qquad (9)$$

This gives the resistance for any length equation (1) when the following are known: the area of the column, velocity of the water, specific resistance of the water at 20 deg. cent., the initial temperature of the water, and the current through the column.

Equation (9) shows something that was practically self-evident, that is, as the current I changes, it is possible to keep the resistance all along the column constant by changing V, the velocity of the water. As can readily be seen, the velocity must vary as the square of the current—as would be expected.

If the maximum effective value of the current to be used is fixed and the allowable temperature rise (if a glass tube were used instead of rubber this temperature could be 100 deg. cent.) of the water decided upon, then the distribution of voltage down the column can be computed. When this is done the pitch

2. From tests by Applequest and McKenny, M. I. T., 1912. *Pender Handbook*, (edt. 1922), p. 1356.

of the helix can be changed in such a manner that the potential of the water column at all points is the same as the space it occupies between the two plates—under these conditions the shielding is ideal. In order for the voltage gradient of the column to remain constant it is only necessary to keep the temperature of the ingoing and outgoing water constant. The temperature of the ingoing water is easily adjusted. The temperature of the outgoing water is controlled by regulating the velocity. To tell when the temperature was correct a thermometer could be placed in contact with the water at the discharge end and read by means of a telescope. However, a more direct method than this was employed. A wattmeter was connected in the ground circuit of the water column as shown in the diagram of connections. One coil carries the current that passes through the water resistance and the other coil of this wattmeter with suitable resistance is connected across the low voltage primary of the high voltage transformer. The wattmeter reading will be

FIG. 3—VIEW OF HIGH-VOLTAGE WATTMETER AND AUXILIARY EQUIPMENT

At center on right is insulated screen cage enclosing wattmeter instrument and milliammeters; at the top on right is shielded water column resistance; in center at bottom is hydraulic apparatus, and at left is cage containing crest voltmeter and ohmmeter

an indication of the amount of power absorbed by the water column. Thus, for example, if the conductivity of the supply water remains constant and the line voltage is doubled, the reading of this wattmeter will be increased four times which means that to keep the temperature constant there must be four times the quantity of water flowing through the hose. This, of course, will require a certain increase in water pressure. By knowing the constants of this wattmeter and the water flow in terms of the pressure-gage reading, a scale was made for the wattmeter so that instead of reading watts the wattmeter indicates the pressure necessary to keep the temperature of the outgoing water constant. This works out very well under actual test; with the conductivity of the supply water constant the resistance of the water column was determined at various voltages and found to be practically constant. This, of course, means that the voltage gradient down the column remains constant. Assuming that the temperature resistance equation is not altered by the introduction of salt into the water, the value of R_{20} can be changed, thereby uniformly increasing r throughout the length of the column. This will, of course, increase I; hence V must be correspondingly increased. This will not change the voltage distribution down the column and therefore will not alter the shielding. In other words, the resistance of this resistor can be uniformly changed throughout its length without changing its dimensions.

The necessity of the exact matching of the field established by the water column with that between the two plates has been found by integrity tests. On account of the relatively large charging current through the line coil of the wattmeter, it requires only an extremely small capacitance current through the other coil to produce a fair sized deflection, which of course is error-reading. Any field picked up or supplied by the water column will cause such an error. To test for correct shielding, a reading of the line wattmeter is taken at a certain water conductivity and line voltage; then with the line voltage kept constant, water of, say, twice the conductivity is used, which should double the original wattmeter reading if the shielding is correct. The only thing that is changed during this test is the conductivity; the physical dimensions of the circuit and the voltage gradient down the column remain unaffected. If the wattmeter reading is not proportional to the current in the potential circuit at constant line voltage, there is error-reading due to improper shielding. However, as discussed in a previous paper on the high voltage wattmeter,[3] an error-reading can also be the result of improper shielding of other parts of the circuit besides the water column. After the present water column was designed and built the above test was applied and the shielding was found to be correct within the limits of observations. Besides the above test, another obvious advantage of being able to change the resistance of this wattmeter multiplier is to greatly increase the wattmeter readings at the lower voltages.

The change in the resistance of the water column is accomplished by the introduction of common salt into the water. The water supplying the pump is drawn from two tanks, one fresh and the other a salt solution. The valves on each line from these tanks are connected together in such a manner that as one opens the other closes. When the valves are once set the mixtures remain constant to a surprising degree of steadiness. The gear pump no doubt aids considerably in the mixing process; also, the bypass valve is never completely closed when the salt solution is being used. The hydraulic system of controls must be such that the pressure, and hence, the flow, can be changed without affecting to any great extent the conductivity. One thing necessary in order to do this is to maintain the level of the water in the two supply tanks constant and

3. "Power Measurements at High Voltages and Low Power Factors," by Joseph S. Carroll, Thomas F. Peterson, and George R. Stray, JOURNAL A. I. E. E., p. 941, Oct. 1924.

equal at all times. Also the change in conductivity should not alter the flow; however, as the conductivity is changed the flow must be controlled to keep the temperature constant.

The Ohmmeter

The resistance of this wattmeter multiplier is determined in the following manner (see diagram of connections) while the high voltage is on: A storage "B" battery of about 100 volts is inserted in the ground end of the water column. This battery forces a direct current through the galvanometer G_1, the choke 1, up through the water column, through the secondary winding of the high voltage transformer, to ground and back to the other side of the battery. This direct current goes only through the galvanometer whereas the alternating current is allowed to pass only through the 10 m. f. condenser in parallel with the galvanometer and choke. Knowing the voltage of the battery and the calibration of the galvanometer, the resistance of the water column can be determined. Of course, the resistance of the transformer winding and choke must be subtracted and the drop across the condenser be corrected for if necessary. Knowing the resistance of the water column and the effective value of current through it, the total effective line voltage can be computed. The values of voltage obtained in this manner check on an average within 0.5 per cent of the voltage as measured by the voltmeter coil within the transformer. This difference at present is about the limit of our accuracy.

To obviate the necessity of insulating the apparatus at the ground end of the water column in order that the current through the galvanometer shall have only one path to ground, a connection is made from the battery through a resistance R_1 and to a point C on the lower end of the water column. The current in this circuit flows from C to the ground at D. The resistance of R_1 is made such a value that the drop across it is the same as the drop across the galvanometer and choke. This puts the point B at the same d-c. potential as C so that there is no current flowing between B and C and the only current through the galvanometer is that through the water column. To test for the equality of potential of B and C, a single-pole double-throw switch is connected in the circuit so that the galvanometer can be connected between these two points with a choke 2 in series. The resistance R_1 is then adjusted until there is no current through the galvanometer and then the switch is thrown back to connect the galvanometer in its normal position. The switch H is, of course, closed during this operation of balancing. This balance when once made remains the same throughout the test; the ratio of the resistance between C and D, and A and B is the same for all conductivities. The resistance of the water between B and C is never less than 50,000 ohms and for the higher voltages it is 500,000 ohms. The resistance from C to D is about half that between B and C and is sufficient to limit the current drawn from the battery to a reasonably small value. Since the resistance of the galvanometer G_1 is only 14 ohms and that of the choke 1 is about 7500 ohms, no correction is necessary when the galvanometer is shifted from one place to the other. The a-c. drop across the condenser is 16 volts with a current of 0.060 amperes at 60 cycles; however the secondary of an audio transformer keeps the galvanometer free from vibration due to this voltage.

The Crest Voltmeter

The crest values of voltage are determined by multiplying the effective values by the crest factor. This crest factor is determined as follows: The current through the water column has the same wave-form as the line voltage so that an ordinary voltmeter inserted in the ground end of the water column will give a replica of the total line voltage. By means of a synchronous driven contactor, a condenser is charged with the crest value of this effective voltage, the ratio of these two being the crest factor. The voltage of this condenser could be determined directly by means of an electrostatic voltmeter; however the time of taking readings does not permit the use of such slow acting instruments. In place of such a voltmeter, a practically instantaneous self-balancing potentiometer was used in which the voltage of the condenser is read by means of the ordinary quick acting d-c. voltmeter. Before the operation of this potentiometer is taken up, a brief description of the different parts will be given.

The current through the d-c. voltmeter is furnished by a storage "B" battery of about 135 volts. This current also passes through the plate circuit of a 201A vacuum tube, $V\,T_1$ (see diagram), and through the winding G on an iron core choke. The filament current of $V\,T_1$ is a-c. and is furnished by a specially designed constant current transformer. In parallel with this filament are the windings E and F of a choke made up of laminated iron rings; the winding E is around half of the rings and F is around the other half. The windings G, H and J are around all of the rings. The coils E and F are connected in parallel in such a manner that the flux set up by the current through them is in opposite directions and hence there is no voltage induced in the other windings. There is a positive bias put on the grid of $V\,T_1$ to reduce its filament to plate resistance. $V\,T_2$ is also a 201A tube and might be called the detector tube since it detects any difference between the potential of the condenser C_1 and the voltage at the terminals of the d-c. voltmeter. The filament of this tube is lighted with a four-volt storage battery. Sixty-five volts of the storage "B" battery are used on the plate of this tube; in this plate, circuit is the coil H consisting of 10,000 turns of No. 36 B. & S. d. s. c. copper wire. There are 250 turns in coil J which are used to produce a field almost equal and opposite to that of H.

With this description of the apparatus, the operation will now be taken through step by step. The alternating current through the water column resistance on its way to ground passes through the a-c. voltmeter and its non-inductive shunt—the shunt being necessary on account of the current carrying capacity of the voltmeter. The effective value of the voltage across the voltmeter is kept about 50 volts on the 75-volt scale by means of the shunt resistance; however, this is only for the convenience of reading and the operation over a range from 35 to 70 volts gives accurate results. The crest of this voltage is picked off by the synchronous contactor and charges the condenser C_1. If to begin with, this potential is not the same as that across the d-c. voltmeter there will be a current through the galvanometer G_2; in this case the current through the bias winding J is changed by means of the potentiometer N until there is no current through G_2. This is the only adjustment necessary and when once set it requires but very little changing. With the deflection of G_2 zero the d-c. voltmeter gives the potential of the condenser C_1. This reading divided by the reading of the a-c. voltmeter, is of course, the crest factor. Now, suppose that the a-c. voltage decreases; this will lessen proportionately the potential of C_1 and the d-c. voltmeter will momentarily be the same as before; a current then will flow through G_2, R_3 and R_2 for a very short time making the grid of $V\,T_2$ positive with respect to the filament. This will increase the plate current which is also the current through the coil H; this increases the saturation of the iron core and reduces the reactance of the windings E and F. Since these windings carry about 80 per cent of the constant current from the filament transformer, the filament current of $V\,T_1$ will be reduced. This increases the filament to plate resistance which will in turn diminish the current through the d-c. voltmeter and bring down the voltage across it until it is the same as the potential of C_1. In case the a-c. voltage rises, just the reverse of these operations will take place. The coil G in series with the d-c. voltmeter might be called a tickler winding; the number and direction of turns are such that the change in the current through the voltmeter produces just sufficient change in the saturation of the iron to keep the voltmeter where it is put without maintaining extra current through the coil H by a difference of potential between C_1 and the d-c. voltmeter. A very good test of this is to disconnect C_1 from the contactor while it is charged; the needle of the d-c. voltmeter stands practically still. If part of the charge is allowed to leak off the condenser, the voltmeter will immediately drop to that potential and remain there when the leak is taken off—thus demonstrating the minute amount of current necessary through R_2 to operate the system. One thing that aids considerably in the sensitiveness of this apparatus is the fact that the vacuum tube $V\,T_1$ is operated where the plate current is most sensitive to a change in filament current; for example, a change in filament current from 200 milliamperes to 215 milliamperes will change the plate current from about 3 milliamperes to 6 milliamperes with the 16,000 ohms of the voltmeter in series.

The condenser C_2 of 1 μ. f. is necessary in order to smooth out a small component of a-c. on account of using 60-cycle current to light the filament of $V\,T_1$. These ripples produced an a-c. potential between the grid and filament of $V\,T_2$ which was rectified leaving the grid negative and thus causing trouble. The resistance R_3 was found necessary to damp out very low frequency oscillations or hunting between the two condensers C_1 and C_2, caused mainly on account of the time lag in the change in temperature of the filament of $V\,T_1$.

The transformer furnishing the current for $V\,T_1$ was designed to take care of any reasonable fluctuation in line voltage. Since $V\,T_1$ is sensitive to slight changes in filament current, any change in line voltage would have to be adjusted for by $V\,T_2$ which is not the primary duty of this tube. This transformer furnishes practically a constant current in the secondary circuit with a 10 per cent change of primary voltage. One part of the secondary S_1 is wound on a practically saturated iron core. In series with this winding and 180 deg. opposite in phase is a winding around an air-gap magnetically in parallel with the saturated core of the other winding. The winding S_2 gives about half the voltage of S_1. With a change in primary voltage the flux across the air-gap changes at about twice the rate as that through the iron core; in this way the two changes just offset each other. The adjustment of the two secondary windings is made in an over-all manner by means of a milliammeter in the plate circuit of $V\,T_1$. Of course the secondary current of this transformer is far from a sine wave but this is in no way a handicap.

The crest voltmeter circuit may seem elaborate; however, it has been found worth while in order to have an electrostatic instrument with the advantages of the modern highly damped sensitive d-c. voltmeter. The operation of this crest voltmeter is simple and reliable and to further improve its simplicity, it is hoped that sometime the synchronous contactor can be replaced by a special vacuum tube.

Another feature that has been added to the equipment is a 230-ft. line of hollow copper conductor. With this conductor it is possible to electrically cut out both strings of insulators as shown in the diagram and hence measure only the losses from the conductor. By changing the connections, the insulator losses may be included with the loss from the conductor or else they may be measured separately. The insulators are cut out by supplying the power to them directly and not through the wattmeter. The power is supplied to the string at the far end by running an insulated wire through the hollow conductor and connecting it back of the first insulator.

The work this year has been largely development

work; however, several tests were made on the three 230-ft. lines in the rain and also in dry weather. The results of the tests substantiate very well the work done with the wattmeter last year. During the rain tests, the fact was again emphasized that a rain test does not mean much unless the rate of rainfall is determined because the power loss varies considerably with the rate of rainfall. Next year it is planned to have a rainfall indicator and to find the relation between the rate of rainfall and the power loss from the different conductors and insulators.

Encouraged by the success of the present wattmeter, the design of the million-volt wattmeter has been begun. The crest voltmeter and ohmmeter in their present form can be used with but very little change. The main problem will be the fifteen-million-ohm, shielded multiplier.

ACKNOWLEDGMENTS

The present high voltage wattmeter development was made possible through a grant of two hundred and fifty dollars made for the purpose by the National Academy of Sciences from the Joseph Henry Fund.

The cooperation of the Anaconda Copper Co. and the Southern California Edison Co., in furnishing free of charge 500 ft. of 1.125-in. outside diameter, flexible tubular-center stranded copper conductor, made possible the study of the complete segregation of insulator and corona losses from heavy line conductors.

The author wishes to express his appreciation for the assistance given him by members of the graduate class of the Electrical Engineering Department in taking observations and also in some of the actual construction work. Through the work of C. V. Litton and P. F. Schofield the solution of the pitch of the water column by an approximate method was replaced by the exact solution as given in this paper.

Discussion

R. W. Sorensen: When I first saw the diagram of connections shown in this paper I was awed by the apparent amount of large apparatus necessary to construct such a wattmeter. However, I have had the opportunity to stop at Professor Ryan's laboratory and become acquainted with the equipment described in this paper. An acquaintance with the equipment eliminated the impression of bigness which I had received from the diagram and which was perhaps due partly to the high voltages which the equipment will measure. In place of this impression I received a definite picture of the cleverness exhibited by Mr. Carroll and Professor Ryan in handling this problem. For example, the transformer of three windings and a split core, which seems in the diagram to be so large, is actually very small; in fact, it can easily be held in one hand.

The water column, about 16 ft. long, is so arranged between the shielding plates at the ends as to occupy a space approximately 3 ft. in height. The small transformer and the indicating instruments are all mounted on a small table surrounded by a wire cage the dimensions of which approximate 4 ft. high, 6 or 8 ft. wide and perhaps 12 ft. long.

With this knowledge, I found it much easier to read the paper and appreciate what has been done in Professor Ryan's laboratory toward producing practical wattmeters and voltmeters for high-potential measurements.

H. V. Carpenter: Mr. Carroll mentions the integrity tests by which he established the fact that he was able to read with accuracy loads of a watt or two, with a voltage of 150,000. It seems to me the condition is so critical there that a word in relation to his method of establishing the integrity would be interesting. Also regarding the formula given for the resistance of the water column, I would like to ask whether he established it over a wide range of densities and for any materials except common salt.

J. S. Carroll: Ordinarily the man in a measurements laboratory thinks of errors in measurements as a few tenths of a per cent. However, in this case where we are measuring one watt of power at 150,000 volts and the apparent power is of the order of 6000 watts, I frankly admit that we are very well satisfied with an accuracy within 25 per cent of true values. As the load increases the accuracy greatly increases so that at 40 watts we expect the error to be not over two or three per cent. One of the integrity tests used is described in the present paper; that is the double-conductivity test. Another test is described in the Oct. 1924, A. I. E. E. JOURNAL in the paper on Power Measurements at High Voltage and Low Power Factor, by Carroll, Peterson, and Stray. In this test a shielded resistance was inserted in the connection to the line; the value of this resistance was known as well as the line charging current through it from which the power absorbed by it was computed; this increase in power was also measured by the wattmeter. The agreement between the results of the two determinations was very satisfactory. The double-conductivity test was also used in connection with the above test.

In regard to Professor Carpenter's second question, I might say that we have so far tried only a common salt solution and have not gone farther than checking the formula given in the paper in an overall way for the purpose o finding any serious error. We measured the cold resistance of a solution and then calculated what the hot resistance of the water column should be; this result agreed very well with the value obtained under actual operating conditions. On some of these things we wish to make a closer follow-up as soon as we have time.

On the Nature of Corona Loss

BY CLARENCE T. HESSELMEYER[1]
Non-Member

and

JAROSLAW K. KOSTKO[2]
Associate, A. I. E. E.

INTRODUCTION

If a high voltage is applied between two electrodes, experience shows that in any given case there is a limiting voltage below which no loss occurs; a permanent current flows only if the voltage is an alternating one and is then a purely charging current. Above this voltage loss appears, accompanied by the familiar phenomenon of corona; a permanent current flows even in the case of continuous potential, showing that the air space between the electrodes becomes a conducting part of the circuit.

If E is the applied voltage and Q the quantity of

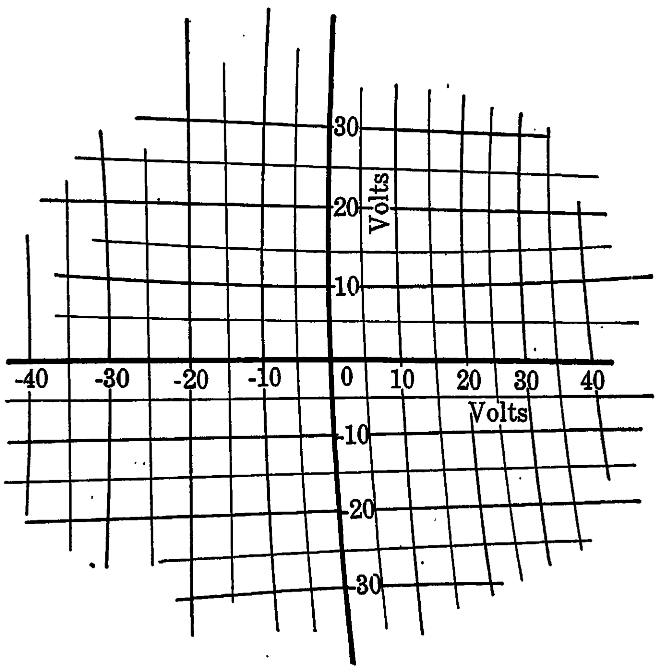

FIG. 1

electricity which has passed in the circuit, then with alternating potentials the relation between E and Q is represented in rectangular coordinates by a closed curve whose area is a measure of energy per cycle. The $E-Q$ relation is therefore of prime importance in the study of corona loss.

A number of such $E-Q$ diagrams of corona loss have been taken, and the results are presented in the first part of the paper. They lead to certain conclusions regarding the nature of corona loss discussed in the second part of the paper.

PART I

The $E-Q$ diagrams were obtained by means of the cathode-ray cyclograph. In this instrument a stream of electrons emitted by a hot filament of a vacuum tube is directed along the axis of the tube by means of a strong electric field. The inside of the opposite end of the tube is covered with fluorescent material which becomes luminous at the spot where the electrons strike it. Along its path, this stream passes between two consecutive pairs of parallel metal plates arranged at right angles to one another.

If the relation of two variables is desired, voltages proportional to these variables at every instant are applied between the corresponding pairs of plates. The electric fields set up by these voltages deflect the ray and cause it to describe a luminous curve on the fluorescent screen. For further detail, the reader is referred to an article by J. B. Johnson, *Bell System Tech. Jour.*, Vol. I, p. 142, Nov., 1922.

On account of the weakness and non-actinic qualities of the light produced by the luminous spot, it was necessary to make all observations visually and record them by tracing on a piece of tracing cloth held against the end

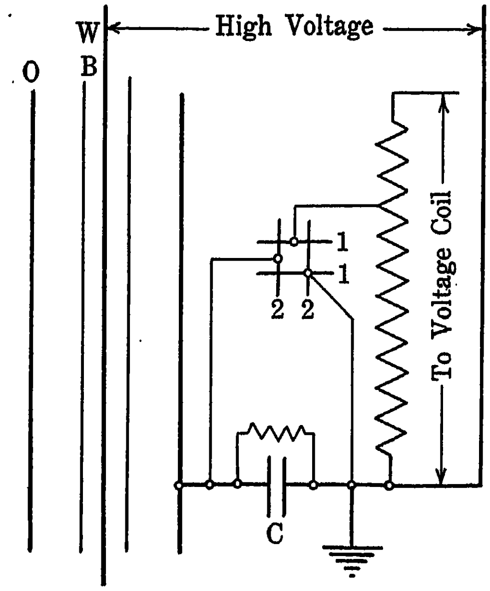

FIG. 2

of the tube by means of a special fixture. In order to calibrate the tube, two sets of readings were made using alternating voltages in one pair of deflectors and known values of direct current voltage in the other pair. From this test a set of coordinates shown in Fig. 1 was plotted, by means of which any $E-Q$ card can be corrected for distortion and replotted in rectangular coordinates. All areas, whether replotted or not, were corrected for distortion.

A typical connection diagram is shown in Fig. 2; W and O are the electrodes (in this case a wire and a cylinder); B is an electrically isolated cylinder the pur-

pose of which will be explained later. 1—1 are deflectors connected across an adjustable portion of a resistance placed across the voltage coil of the high voltage transformer. These deflectors give a deflection proportional to the applied voltage, E. Deflections proportional to Q are obtained by connecting the other pair of deflectors,

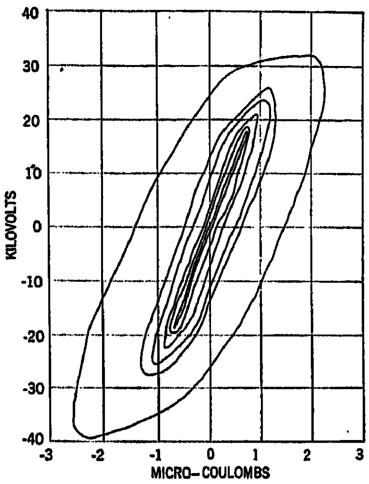

FIG. 3—BARRIER EXPERIMENT—60 CYCLES

No barrier.

2—2, across a large capacitance C, connected in series with the outer cylinder. These deflectors are also shunted by a resistance of the order of a megohm. Without this precaution the plate not connected to the

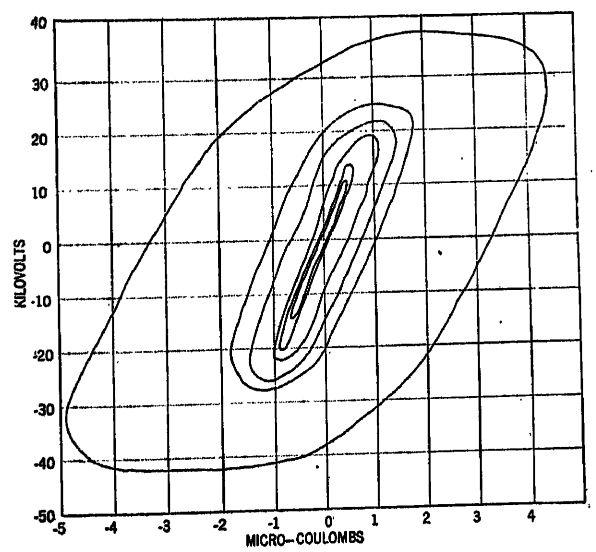

FIG. 4—BARRIER EXPERIMENT—10.5 CYCLES

No barrier.

anode would collect a charge and the spot would drift. Since the action of corona over positive and negative crests is unsymmetrical, there is a tendency for the capacitance, C, to accumulate a unidirectional charge, which is also drained off by this shunting resistance. The diagram itself gives the voltage across this resistance so that the current in it can be calculated and the diagram corrected for it. The effect of this resistance was found to be negligibly small.

Most of the tests were made with the classical arrangement of a wire along the axis of a cylinder. The connection between corona loss and the conduction of electric charges through the air space was studied by placing in the path of the charges, insulated barriers, B (Fig. 2), in the form of concentric cylinders of different diameters. The walls of these barriers were always thin so as not to modify the original field, and it was then of no consequence whether they were made of conducting or insulating materials.

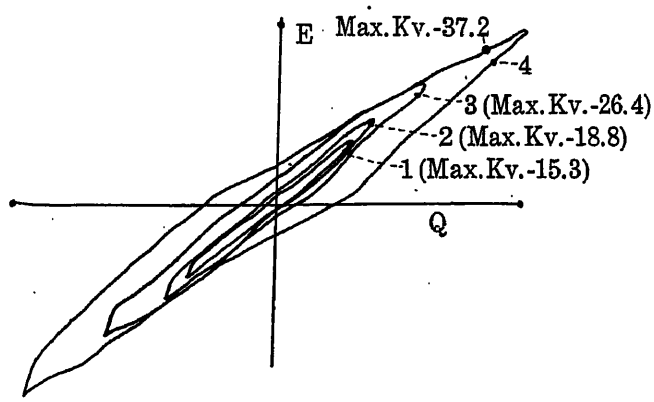

FIG. 5—BARRIER EXPERIMENT—60 CYCLES
0.034-in. diam. wire and 16-in. (mesh) cylinder
Barrier metal cylinder 1¼ in. in diam.

In all cases the wire was of copper 0.034 in. in diameter, and the outer cylinder O was formed of ½-in. mesh wire screen 16 in. in diameter. Figs. 3, 4, 5, 6 and 7 show some of the diagrams obtained with this wire and cylinder arrangement.

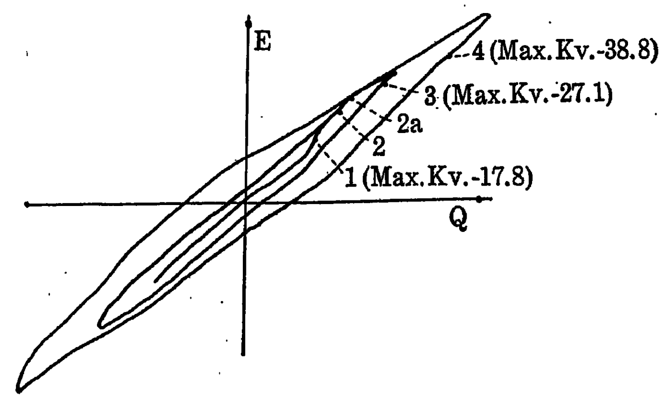

FIG. 6—BARRIER EXPERIMENT—60 CYCLES
0.034-in. diam. wire in 16-in. diam. (mesh) cylinder.
Barrier glass cylinder 1¼ in. diam.

In Figs. 3 and 4, the original cards (taken with no barrier at 60 and 10.5 cycles respectively) were replotted in order to reduce them to a common scale.

Figs. 5, 6 and 7, taken at 60 cycles and all at the same scale, are reproduced without any change; barriers

were of 1 ⅛ in. diameter metal tube, 1⅛ in. diameter glass tube, and 11 in. diameter metal tube, respectively.

Fig. 8 shows $E-Q$ areas (in joules) for the same maximum voltage (28.5 kv.) as a function of barrier diameters.

Fig. 9 is the reproduction of a card taken at 60 cycles on a 230-ft., single-phase line composed of No. 20 copper conductors spaced 36 in. apart. Figs. 10, 11 and

PART II

The general characteristics of the $E-Q$ curves suggest the following explanation of corona loss:[3]

When the electric field acting on a free electron exceeds a certain critial value, the velocity acquired by the electron becomes so great that when it collides with an atom of the air it dislodges other electrons from this atom; that is, it ionizes the air; and if this field is exceeded throughout a certain definite minimum distance from the conductor (critical corona striking distance), visible corona appears.

The liberated ions of opposite sign to that of the wire move towards the wire and can be assumed to reach it

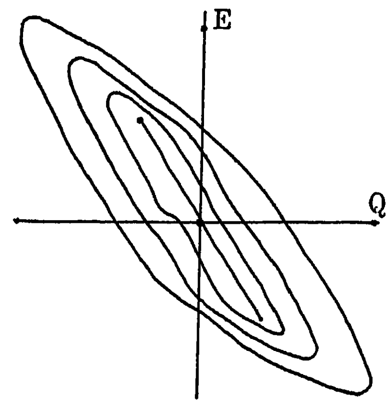

FIG. 9—OUTDOOR LINE—60 CYCLES
No. 20 copper, spaced 36 in., 230 ft. long.

instantly, the zone of active ionization surrounding the wire being always very narrow; the ions of the same sign as the wire move away from it, towards the outer cylinder. To move these ions, energy must be expended by the source of e. m. f. creating the field. *Corona loss is this energy*, regardless of the place where it is expended, near the surface of the wire, or on the boundary of the

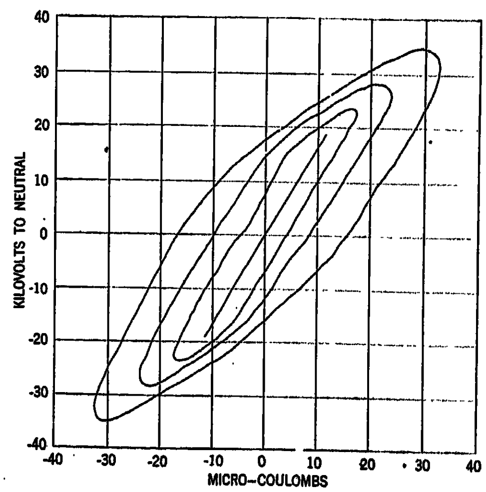

FIG. 10—OUTDOOR LINE—60 CYCLES
No. 20 copper, spaced 36 in., 230 ft. long.

zone of active ionization, or midway between the electrodes; the manifestations of corona perceptible to our senses—light, sound, heat—are caused simply by further transformations of the kinetic energy imparted to the ions by the electric field, and depend on the place

3. See paper entitled "The Hysteresis Character of Corona Formation" by Prof. Ryan and Prof. Henline, JOURNAL A. I. E. E., p. 825, Sept. 1924.

and the mode of these transformations; within the zone of ionization, the energy is mostly spent in the invisible process of ionization by collison; if the impact of an ion against an atom of the air is strong enough to disturb the equilibrium between the nucleus and an electron of the atom, but not sufficiently strong to separate them permanently, the electron returns to its original position by a sort of vibratory motion, giving up energy acquired from the colliding ion in the form of light. Outside of the ionizing zone, the path of an ion is marked by a series of collisions with the atoms of the air; at each collision a part or the whole of the kinetic energy of the ion is transferred to the atom; if the ion strikes a solid electrode, its kinetic energy is converted into heat. If the applied e. m. f. is alternating, the ions in the air space move as alternately positive and negative waves; an outgoing wave meets a return wave of opposite sign; in the ensuing process of recombination, the energy of the ions is radiated in the form of light.

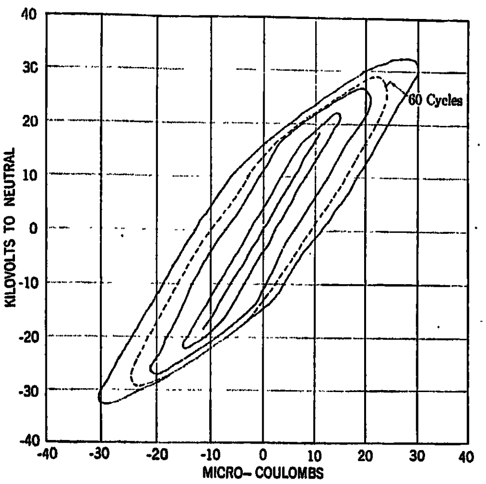

Fig. 11—Outdoor Line—120 Cycles
No. 20 coppor, spaced 36 in., 230 ft. long.

For simplicity, it will be assumed that positive and negative corona phenomena are identical.

In the corona caused by a continuous potential, the unidirectional flow of ions across the air space between the electrodes constitutes a true current in the circuit containing the applied e. m. f. The power expended in corona originates in the cooperation of this corona current with the applied e. m. f. In the corona excited by an alternating potential, a wave of ions may not cross the distance between the electrodes before the reversal of the field; in this case the to-and-fro motion of the waves of ions in the air space sets up a motion of electric charges induced by electrostatic induction in the circuit connecting the electrodes and containing the applied e. m. f.; the action of this e. m. f. on these induced charges corresponds to the corona energy loss.

If a barrier is placed infinitely close to the outer cylinder, we have an exact equivalent of the system of a wire in a cylinder, without any barrier; if there is no barrier, an ionic charge crossing the air space and arriving at the outer cylinder will neutralize an equal and opposite charge on this cylinder; if a barrier cylinder, infinitely close to the outer cylinder, is present, these two charges will remain separate but infinitely close to one another; in both cases their combined external action will be zero. For the sake of generality, it is convenient to assume that a barrier cylinder is always present.

As before mentioned, the action of corona is to release into the space a charge of ions; an equal charge of opposite sign goes to the wire. By analogy with the vacuum tube terminology, the former charge will be called "space charge;" at any given moment it may be located entirely in the air, or entirely on the barrier, or be distributed in the air and on the barrier. Let $-Q$ be the charge on the outer cylinder and q = charge on the wire; the total charge of the system being zero, the space charge x is given by the relation

$$x + q - Q = 0$$

hence $x = Q - q$. Let E be the e. m. f. applied between the wire and the outer cylinder; with the barrier cylinder placed between the wire and outer cylinder, the charge $-Q$ can reach the latter only through the circuit containing E; hence this charge on the outer cylinder is the same as the charge Q in the E-Q diagram.

The amount of space charge is controlled mainly by two factors: the variation—in time—of the field near the wire, and the initial ionization (number of free ions at the moment when the field reaches the ionizing value); the field here means the resultant of the field due to the applied e. m. f. and the field set up by the space charge.

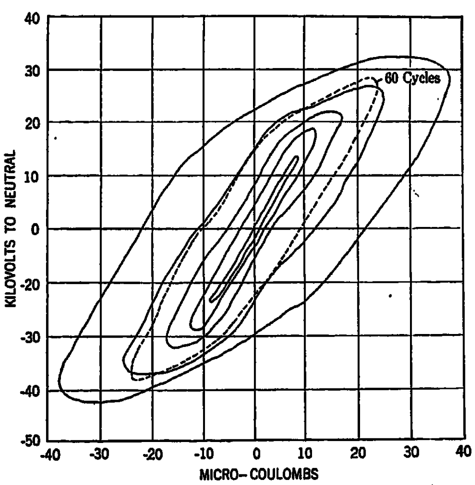

Fig. 12—Outdoor Line—10.5 Cycles
No. 20 copper, spaced 36 in., 230 ft. long.

It will be assumed[4] that, as a limiting influence, the second factor is negligible relative to the first, *i. e.*, that the antecedent ionization is sufficient to cause an instant and unlimited ionization by collision, unless checked by the drop of the field caused by the reaction of the space charge; in other words, as long as corona

4. See Footnote No. 3.

lasts, the action of the space charge is to maintain the same distribution of the field in the zone of active ionization as that which exists at the moment when corona starts for the first time. This hypothesis means that during the existence of corona, the charge on the wire must remain constant and equal to the charge which it has when corona first starts; if the initial critical corona voltage is E_0, and the capacity of the wire to the outer

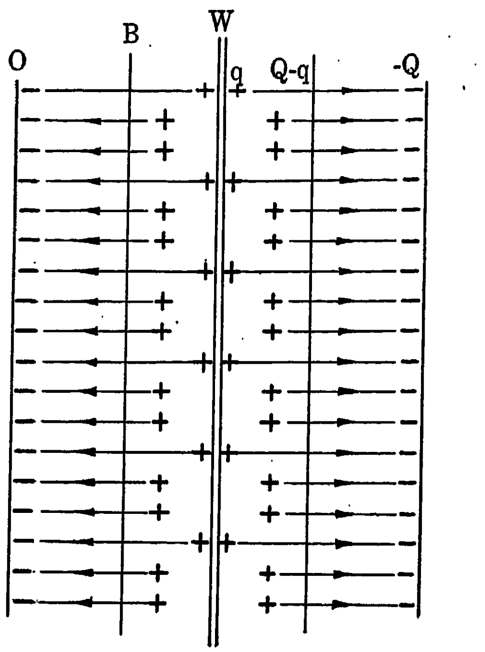

FIG. 13

cylinder is C, then this charge is $Q_0 = C\,E_0$; therefore,

$$q = Q_0 \qquad (1)$$

Fig. 13 shows the distribution of charges. The charge q on the wire, with an equal and opposite charge $-q$ on the outer cylinder, set up a potential difference q/C; the space charge $Q - q$ and an equal and opposite charge on the outer cylinder set up a potential difference E'; the sum of these potential differences must at all times be equal to the applied voltage E; therefore,

$$q/C + E' = E \qquad (2)$$

Equation (1) applies only during the portion of the cycle when corona exists; equation (2) holds good throughout the cycle.

For the purpose of experimental verification of the theory it is convenient to study the simple case when the distance between the wire and the barrier is so small that the interval of time required by the ions to reach the barrier is negligible relative to the period of the supply voltage. The entire space charge is then on the barrier; if the capacity of the condenser consisting of the barrier and the outer cylinder be denoted by C', the potential difference E' due to the space charge $Q - q$ is $(Q - q)/C'$, so that equation (2) becomes

$$q/C + (Q - q)/C' = E \qquad \textbf{(2a)}$$

The equation of the E-Q curve when corona exists is obtained by substituting $q = Q_0 = C\,E_0$ [equation (1)] into equation (**2a**); this gives

$$E = Q/C' + E_0\,(1 - C/C') \qquad (3)$$

This is a straight line, 1—1, Fig. 14, of slope $1/C'$, which passes through the point C of initial corona (*i. e.*, starting for the first time, without any space charge).

When the voltage reaches its maximum value at M and begins to decrease, corona immediately stops. For, beyond M, the continuation of corona would mean that in equation (2), q/C would remain constant by equation (1), while E' would increase on account of the increasing space charge, the net result being an increase, not a decrease, of the applied e. m. f. E.

After corona stops, the space charge remains constant, *i. e.*, $Q - q =$ (constant); the equation of the E—Q curve for this part of the cycle is obtained by substituting $q = Q -$ (constant) in equation (**2a**); this gives

$$E = Q/C - (1/C - 1/C') \times \text{(constant)}$$

This curve is a straight line $M\,N$ of slope $1/C$, *i. e.*, of the same slope as the precorona line $O\,C$ of the condenser formed by the wire and the outer cylinder.

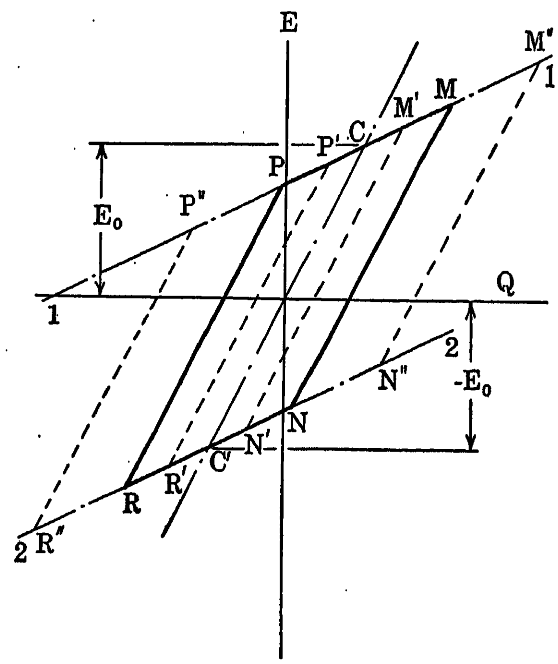

FIG. 14

By reason of symmetry, corona of the opposite sign will follow the straight line 2—2, parallel and symmetrical to the line 1—1. This line passes through the point C' symmetrical to C and corresponding to the critical voltage $-E_0$; but corona begins earlier, at N, because the space charge on the barrier now assists the applied voltage E in producing the ionizing gradient (field).

If the maximum of the voltage corresponds to the

points, M' or M'', the loops, $M'N'R'P'$ and $M''N''R''P''$, may have very different appearance.

Let E_m be the maximum value of the applied voltage; the area of the $E - Q$ loop is $4\,E_0\,(E_m - E_o)\,(C' - C)$.

The characteristic features of the loop of Fig. 14 are well in evidence in Figs. 5 and 6 where the diameter of the barrier cylinder is small enough to justify the assumption of the instantaneous transfer of ions from the wire to the barrier, yet large enough to minimize the effects of various irregularities such as eccentric location of the wire relative to the cylinder, vibration of the wire, dirt on its surface, etc.

The simplified diagram is independent from the frequency; it is also not affected by the wave shape of E so long as the latter has no multiple peaks.

If it is attempted to extend this construction to the case where the barrier coincides with the outer cylinder, the lines 1—1 and 2—2 become horizontal, and the loop extends to infinity. This absurd result is due to fact that so long as the charge on the wire is constant, the increment of the space charge is equal and opposite that of the outer cylinder, and, being infinitely close to the latter, completely neutralizes it so that there is nothing to prevent an unlimited amount of corona discharge. In this case the finite velocity of the space charge cannot be ignored.

Suppose, now, that the velocity of ions is not infinite; then a space charge may exist not only on the barrier but in the space between it and the wire. If the field were unmodified by the presence of the space charge it would be easy to predetermine the motion of an ion; the field at a distance x from the axis of the wire is

$$g_x = \frac{E}{x \log \frac{R}{r}}$$

where R and r are radii of outer cylinder and wire. Therefore, the velocity being proportional to the field, the distance x is determined from the equation

$$\frac{d\,x}{d\,t} = \frac{a\,E}{x \log \frac{R}{r}}$$

where a is a constant and E is a function of time t. This equation, integrated for the case where $E = E_m \cos \omega\, t$, gives

$$\frac{x^2}{2} - \frac{x_o^2}{2} = \frac{a}{\log \frac{R}{r}} \int_{t_0}^{t} E\,d\,t$$

$$= \frac{a\,E_m}{\omega \log \frac{R}{r}} \quad (\sin \omega\, t - \sin \omega\, t_0)$$

where $x_0 = x$ at the boundary of zone of ionization from which the ion starts and t_0 = time at which it starts. This relation is shown in Fig. 15 for a 0.034-in. diameter wire in a 11-in. diameter cylinder. The abscissas E_0/E_m give the ratios between the critical corona voltage E_0 and the maximum applied voltage E_m. The ordinates show the maximum travel of ions: the upper branch, for the ions discharged as soon as the voltage reaches the value E_0, increasing, and corona begins; the lower branch, for the ions discharged when the voltage passes the value E_0, decreasing, and the corona is on the point of stopping.

However, the study of the experimental $E-Q$ curves shows that the field is profoundly modified by the space charge; the analytical treatment of this case with alternating potentials is a difficult problem; but it is easy to explain all the peculiarities of the experimental curves, as affected by the voltage, frequency, etc. Since these peculiar features are of no importance except as a proof of the validity of the theory, only a few of them will be analyzed below.

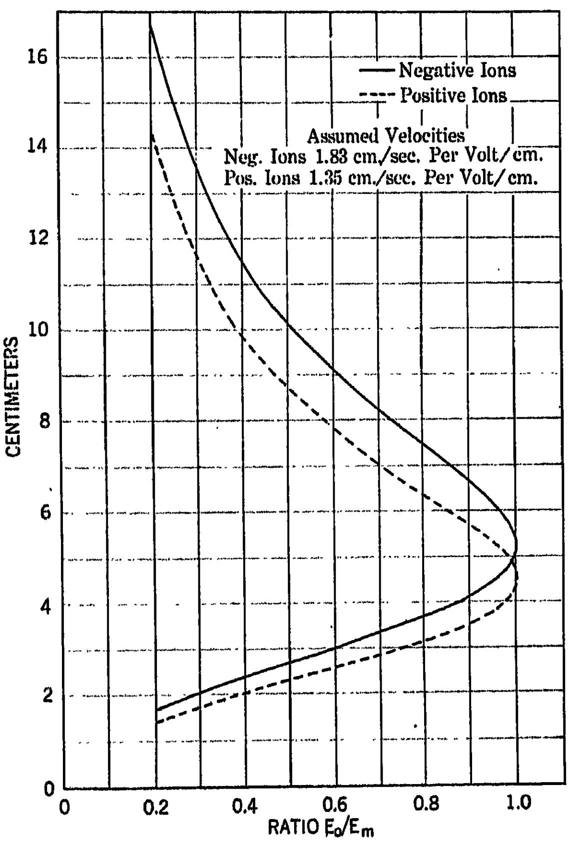

Fig. 15—Travel of Ions in a Radial Field

(0.034-in. diam. wire in an 11-in. diam. cylinder) E_o = critical corona voltage = 16.4 kv. at 60 cycles (maximum).

Experiment gives a loop such as shown in Fig. 16. Assume that at M, where the voltage is maximum, the polarities are as shown in Fig. 13. Corona stops at the point A, where Q passes through the maximum. For, if x denotes the space charge, we have $Q = x + q$; as long as corona exists, q is constant and x increases; therefore Q increases; as soon as corona stops, x remains constant and q decreases; therefore, Q decreases.

The applied voltage at A, where corona stops, is necessarily higher than the critical value E_0, because the action of the space charge is to oppose the field at

the wire due to the applied voltage. After corona stops, the space charge $x = Q - q$ remains constant, *i. e.*, $d\,Q = d\,q$, and the slope of the $E - Q$ curve results from equation (2):

$$\frac{d\,E}{d\,Q} = \frac{1}{C} + \frac{d\,E'}{d\,Q}$$

At first the potential difference E' decreases because the space charge approaches the outer cylinder. Be-

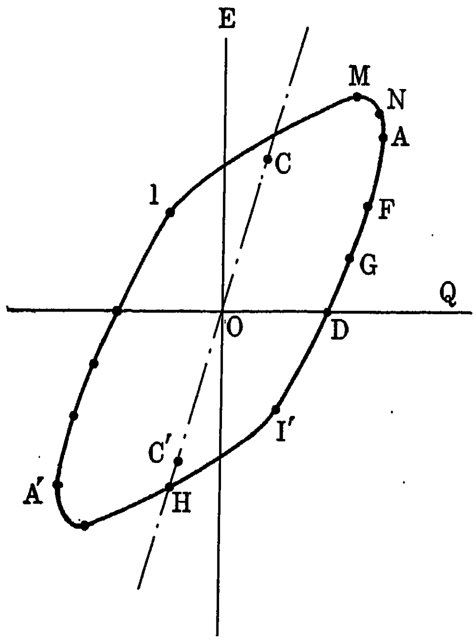

FIG. 16

yond M the decrease of E is small while that of E' is finite; there must be a compensating increase of Q; at A the decrease of E is just equal to that of E'; beyond A, E decreases faster than E', as shown by decreasing Q. At A, $q = Q_0$, and is positive; at D, where $E = O$, q is already negative, as otherwise the sum of q/C and E' could not be zero; therefore, there exists a point F where $q = O$; at this point the field near the wire reverses; with the increasing negative q the region of reversed field increases, gradually overtakes the ions of the space charge, and causes them to flow back to the wire; the rate of decrease of E' diminishes and soon E' begins to increase; since the space charge now cooperates with the applied e. m. f. in setting up the field near the wire, the ionizing gradient is soon reached and corona discharge begins at I' before E reaches the critical value E_0. At the point G, where E' ceases to decrease and begins to increase, $d\,E' = O$ and the slope is $1/C$; at this point the tangent is parallel to the precorona $E-Q$ line $O\,C$.

At I' the corona discharge suddenly releases into the air space a negative charge, while an equal positive charge goes to the wire; the negative ions meet and discharge the residual positive space charge so that the net result is as if this residual positive charge were suddenly transferred to the wire; the variation of E' caused by this sudden transfer must be balanced by an equally sudden variation of Q; this explains the more or less abrupt change of the slope of the $E-Q$ curve at I'. Beyond I' the new charge gradually discharges and supersedes in the air space the residual space charge, at A' the negative space charge is maximum; corona stops, as at A, and so on, throughout the cycle.

If the frequency is low, the ions of the space charge will have time to reach the barrier; at very low frequencies the amount of space charge in the air will be small relative to the charge accumulated on the barrier, and conditions of Fig. 14 will be approximated; at very high frequencies the ions will have no time to move from the wire beyond the corona-striking distance; the effect will be as if the barrier were close to the wire; the $E-Q$ loop will again be as in Fig. 14, but this time with a very small area. As at all frequencies the area

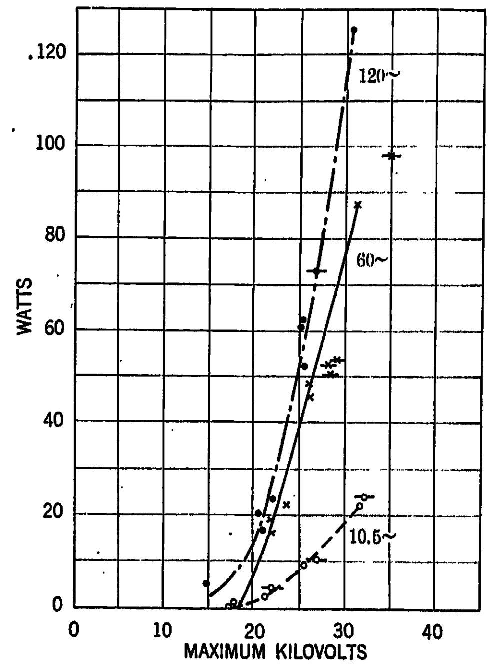

FIG. 17—CORONA LOSS—HIGH-VOLTAGE WATTMETER READINGS AND CYCLOGRAMS SHORT OUTDOOR, SINGLE-PHASE TRANSMISSION LINE

No. 20 copper conductor, spaced 36 in., 230 ft. long

Wattmeter Readings	Cyclograms
o 10.5 cycles	– o – 10.5 cycles
× 60 "	– × – 60 "
. 120 "	– . – 120 "

is controlled by the same factors, *viz.* the amount and the extent of travel of the space charge, we can say; from very high frequencies to very low ones the area increases from nearly zero to a maximum corresponding to the sharp-cornered loop whose construction was given in connection with Fig. 14.

In the practical case for high frequencies, because of the formation of a very open brush pattern wherein the brushes shield the intervening spaces preventing all corona, the ions returning to the conductor are few compared with the ions of both signs remaining in the brush-streamers, the space charge becomes negligible and the phenomenon changes over to one of ordinary

conduction. In air, at common pressures and temperature, laboratory studies to date indicate that the space-charge type of corona formation disappears at a frequency of about 5000 cycles.[5]

With the same outer cylinder, the greater the diameter of the barrier the greater is the extent of the travel, therefore, the greater the area of the loop; but only up to a certain limit: if the diameter of the barrier becomes so great that the number of ions reaching it begins to decrease, its influence on the area becomes less and less pronounced, and vanishes altogether when ions cannot reach it at all.

The curves of Fig. 8 confirm these statements: the low frequency curve lies above the high frequency curve; when the diameter of the barrier increases, the area increases, but at a gradually diminishing rate. Points denoted by ⊙ refer to a test made with the barrier cylinder formed of ¼-in. mesh wire screen; their displacement from the respective curves shows distinctly that the screen, like the grid in a vacuum tube, is not a perfect barrier in the path of the ions. Double points for 1⅛-in. diameter are taken from two tests.

The arrangement of a wire in a cylinder was used on account of its theoretical and experimental simplicity, but the foregoing conclusions are not specific to this arrangement. In all cases of corona there is a space charge whose action is always of the same general character. An $E-Q$ loop is bounded by two distinct kinds of curves, each of a more or less constant slope, corresponding to a continuous variation of physical elements, but with a sort of discontinuity and an abrupt change of slope at the junction points, due to the sudden appearance and disappearance of corona. Curves of Figs. 9, 10, 11, and 12 show these general characteristics; in Fig. 17 the loss computed on the basis of Figs. 10, 11, and 12 is compared with the loss directly measured with the high voltage wattmeter, and the agreement is very satisfactory.

Discussion

R. W. Sorensen: The peculiar curves for Fig. 1 of this paper have to be used in charting the results because a piece of tracing cloth, stretched over the end of the cathode-ray tube, must have lines, as shown, drawn on it to correct for the curvature of the tube and the distortion of the wave.

H. J. Ryan and J. S. Carroll: In the paper on The Hysteresis Character of Corona Formation, by Henline and Ryan,[1] presented a year ago at the Pasadena Convention of the Institute, the authors, in arriving at the existence of a space charge about a conductor in corona, worked at a disadvantage because they had not actually located the radial position of such space charge with respect to the conductor. During the past year two of our graduate students, Mr. Hesselmeyer and Mr. Kostko, proposed to study the radial location of the space charge by the simple plan of a concentric barrier that would limit the radial distance of the space charge from the conductor surface. They would use an isolated barrier cylinder mounted concentrically as specified in their paper; they would obtain the corresponding $E-Q$ relation and then change the radius of the barrier and obtain the $E-Q$ relation again. This plan would be continued over a wide range for the radius of the barrier in order to determine the manner in which the character of the $E-Q$ relation would change with the barrier radius. The purpose of this undertaking was to find out whether the character of the $E-Q$ relation, when barriers were used that bound the space charges to definite radial positions, would approach the character in form and area of the $E-Q$ relation as found for widely separated parallel conductors surrounded by no barriers.

When the work was completed and this paper was prepared by the authors and studied by us, the following point of view developed: The areas in units of energy, given by the Hesselmeyer-Kostko $E-Q$ diagrams, could be expressed in terms of the voltage and the capacitances of the conductor to the space charge and of the conductor to the grounded cylinder or neutral plane. The corresponding power would be the product of the energy by the frequency. Henline and Ryan, in their paper a year ago, had given the corresponding equation for the energy per cycle in terms of voltage and but one value of capacitance, viz., that of the conductor to the neutral plane. It was manifest that, by combining these equations, one could isolate the value of the capacitance of the conductor to the space charge.

Mr. Kostko then derived the equation for the power lost in corona using a barrier, as follows:

$$P = 4 f C (E E_0 - E_0^2) \frac{1}{\dfrac{C''}{C'} - 1} \tag{2a}$$

wherein

E, is the value of the crest voltage,
E_0, the value of the critical voltage,
C, the capacitance from conductor to neutral,
C'', the capacitance from conductor to the space charge, and
f, the frequency.

The corresponding equation given in the Pasadena paper a year ago, wherein the term C'', capacitance of conductor to space charge was not used, was:

$$P = 4 f C (E^2 - E E_0) \tag{2}$$

By combining and reducing these equations the value of the capacitance of the conductor to the space charge was found to be:

$$C'' = C \left(\frac{E_0}{E} + 1 \right) \tag{3}$$

If the radial distance from the conductor to the cylindrical space charge be D_r, and the radius of the conductor r, then the value of C'' will also be:

$$C'' = \frac{0.00368}{\log_{10} \left(\dfrac{D_r}{r} \right)} \tag{2d}$$

By combining equations (2c) and (2d)

$$\log \left(\frac{D_r}{r} \right) = \frac{0.00368}{C \left(\dfrac{E}{E_0} + 1 \right)} \tag{2c}$$

and

5. Eugene D'Hooghe, "The Influence of Frequency on Corona Discharges", Standford University Thesis, June, 1922.

$$\log D_r = \log r + \frac{0.00368}{C\left(\frac{E}{E_0} + 1\right)} \qquad (2f)$$

wherein

D_r and r are in inches

C and C'' are in farads per 1000 feet of conductor.

Equation (2f) was applied to one of the corona loss-voltage curves[1] given by Professor Harding's Pasadena 1924 paper[2] the following locations of the space charge were obtained:

e Kv., r. m. s. swe. to neutral	D_r in inches	Kv. per inch, r. m. s. Conductor to space charge	Between pointed electrodes*

*A. I. E. E. Standardization Rules, 1912.

As a check upon this understanding of the distance of the space charge from a conductor in corona the following trial was made: In front of a pointed electrode at a distance of 9.5 inches a grid of fine wires was mounted. Alternate wires were electrically connected, thus forming two groups of wires each interlaced with the other. To the groups, a 20-volt, dry-cell battery was connected through a portable galvanometer; 60-cycle alternating voltage was then applied between the pointed conductor and grounded plate and the indications of the galvanometer noted as the value of the voltage was raised. The galvanometer indicated that no current was set up through the air between the two groups of wires in the grid until the voltage was raised to an effective value of 110 kv. Thereafter the current increased at the rate of 0.1 microampere per kilovolt until the value of three microamperes was attained at 140 kv. As a slight further increase of the voltage was made, the current through the air between the grid wires rose to eight microamperes. And then, as the voltage increase was continued, there was no corresponding continuation of increase of current. This is precisely the sort of thing that should happen if the foregoing understanding of the existence and position of a space charge about a conductor in corona is correct.

The matter was tried out by another plan: The space charge was reversed while the voltage increased from the critical value E_0 to the crest value, E, in a corresponding interval $\Delta t = t - t_0$. During such interval, Δt, electrons must travel from the conductor to the location of the space charge when the potential of the conductor is negative, and vice versa when positive. When the electrode in corona is the point of a conductor, the resulting luminosities produced by the migration of the electrons as just specified might be intense enough to be visible in full darkness to or near to the radial position of the space charge. On trial, such was found to be the case.

Another reasonable conjecture in regard to action due to the space charge was encountered: Voltage was applied between a pointed conductor and a grounded metal plate. As the voltage was raised, corona filled a conical space that expands from the point toward the plate through distances in relation to voltages that correspond roughly to those given in the above table. As the voltage crests occur the space charges and point potentials have the same sign, while the signs of the space charges and bound charges induced in the grounded plate as opposing electrode are opposite. The consequence is that the intensity of the electric field between the space charge and the point has been reduced and that between the space charge and plate has been correspondingly increased. The outcome must be that, as the voltage is raised, critical electric stress will be encountered in the air between the space charge and the plate beyond which the intervening air must be ionized and rendered conductive. On trial, this too was found to be the case. As the voltage is raised, the faintly luminous cone develops, attached to the point with rounded base thrust forward. Then, as the rise of the voltage continues and the growth of the cone moved its base to a position whereat it was somewhat nearer the plate, a faint pillar of light suddenly extended from the cone to the plate; the air column connecting the point to plate had been ionized and spark-over and arcing followed with slight further increase of voltage.

And so thus far every plan that has occurred for authenticating the existence and position of the alternating space charges established and maintained about a conductor in corona due to 60-cycle voltages when tried out, has resulted in corroboration of the understanding as given.

H. S. Bates: I should like to ask Mr. Hesselmeyer if there will be any means of accurately measuring corona loss? I wish to ask also what is the best method of preventing it?

C. T. Hesselmeyer and J. K. Kostko: The experiments of Prof. Ryan and Mr. Carroll are interesting not only because they prove the existence of a space charge, but also because they suggest experimental arrangements for a quantitative study of the distribution of the space charge and the field. It is easy to set up equations theoretically determining these two elements (Poisson's equation and equation of continuity); but numerical solutions could only be obtained by reducing these general equations to simpler types, based on the results of a preliminary experimental study of the problem.

In the author's opinion the most accurate method of measuring corona losses available at present is by means of the high-voltage wattmeter developed at Stanford University and described in several Institute papers by Mr. Carroll and others.[3] In Fig. 17 of the paper the losses measured with this wattmeter are compared with the losses obtained by a very different method—integration of the E-Q cyclograms—and the agreement is remarkably good.

As indicated by the theory and confirmed by experiment (Fig. 8), it is possible to reduce corona loss by setting up a suitable space charge around the conductor, for instance by enclosing it in a cylinder of a small diameter; it does not seem, however, that this method is suitable for practical applications, at least in the case of a transmission line. A radical reduction of the transmission frequency would result in a reduction of corona loss (Fig. 17), in addition to many other advantages, such as better regulation, etc.

1. In applying these equations it should be remembered that the voltage must be taken at a value sufficiently above the critical voltage to ensure that a fixed brush pattern has been formed and the value of C is a constant as presented in the Pasadena paper.

The Study of Ions and Electrons for Electrical Engineers

BY HARRIS J. RYAN*
Fellow, A. I. E. E.

THE present paper is presented as a contribution to the educational activities of the Institute. Education is often an art and never completely a science. With respect to ions and electrons the science is new and the development of the art scarcely begun,—an art that is bound to undergo rapid evolution. The value of the present paper at best can only exist temporarily.

Physicists and chemists in their studies of the foundation of matter during the last quarter century have been profound students of ions and electrons. Virtually all of their discoveries and results are of direct or indirect value to electrical engineers. The technical and practical uses of knowledge of this character today are extensive. Many important developments have been possible only by its means. And such developments have encountered difficulties that in turn have defined the great need of further knowledge of the same general character. The need for the electrical engineers is being formed, however, in an entirely different mold from that which shapes the requirement of the more general science worker.

In many of the problems originating nowadays in the electrical industries wherein ions and electrons are involved, the physicists and chemists are, in all ordinary circumstances, so loaded with necessary duty in the solution of their own problems that they can rarely afford the time and facilities to come to the aid of electrical engineers. The electrical engineers can, therefore, no longer depend largely upon the physicists and chemists for enhanced results that will enable them to solve their own problems of this class. They will have to do their full share from this time forth to extend knowledge of the facts in regard to ions and electrons and their behavior.

It is of corresponding importance that all advanced students among the incoming generation of electrical engineers be reasonably well equipped with an understanding of the present-day expediency for attacking problems encountered in the electrical industries that require for their solution a clear understanding of the behavior of ions and electrons. It is also recognized that advanced students are not always young men in the colleges. It is important that all,—old and young, wherever situated, should know that it will be most helpful to them and to the electrical industries to acquire a well-founded knowledge of ions and electrons and to learn how to take advantage of every opportunity to apply or to extend such knowledge.

Millikan has splendidly summarized existing knowledge of electrons and ions in his book on The Electron[1], more especially from the point of view of the physicist. J. J. Thomson[2] has rendered a similar service from the point of view of the chemist, though himself a physicist. To these recent classical treaties the advanced student, at the threshold of the subject, is referred.

The following are some of the fundamental facts in regard to electrons that must always hold the attention of many electrical engineers: There are two varieties of electrons, distinguished primarily by the signs of their respective electric charges. The quantities of these charges are alike for each,—4.78 by 10^{-10} electrostatic units, or 1.59 by 10^{-20} ampere-seconds. In respect to other attributes they differ decidedly. The mass of the negative electron is 1/1845 that of the hydrogen atom,—the lightest of all atoms. Correspondingly, the mass of the positive electron is approximately 2000 times the mass of the negative electron, or nearly the same as that of the atom of hydrogen. In atomic structure the positive electrons behave as though they and some of the negative electrons formed the atomic nucleus, while the rest of the negative electrons associated with an atom behave as though they were set in orbits about the nucleus. So far as is known, positive electrons do not exist in the free state. They exist only within the nuclei of atoms accompanied by some of the electrons that bind them in close proximity by electrostatic attraction. The numbers of positive and negative electrons present in the same neutral atom are equal.

The spontaneous breaking up of the nuclei of the heavy (radioactive) atoms into helium atoms and negative electrons is the nearest known approach to the existence of free positive electrons. On the other hand, free negative electrons exist in abundance. An almost endless variety of physical or physicochemical actions may break their orbital bonds to their corresponding atomic nuclei and set them free. The removal of a negative electron from an electrically complete or "neutral" atom results in the presence of one free negative electron, ordinarily called *electron,* and an atom carrying the positive charge of one electron. Such an atom is ordinarily referred to as a *positive ion.* Under all ordinary conditions approaching quiescence, free electrons adhere to atoms, otherwise neutral. The bond is weak and easily broken when the atom is

driven electrically or mechanically through gases, fluids, or near the walls of solids.

All conduction of every character is now known to be due to the movement of positive and negative electrons or more simply ions or electrons, or both. The electrons or ions may be moved mechanically, electrically or electromagnetically. An example of their movement electromagnetically is encountered in the electron jet cyclograph, wherein the electrons liberated from a hot cathode are driven forth in a jet by a strong electric field, and the jet is then deflected transversely by a magnetic field.

It follows that the mobilities of electrons and ions through solids, liquids, gases, and empty space are factors of the highest importance. Far too little is known about these mobilities. Physicists, however, have determined them as the velocities of positive and negative ions in electric fields of unit strength in air and in hydrogen at the usual density occurring at a temperature of 15 deg. cent. and a pressure of 76 cm. as follows:

	Mobilities in cm. per sec. in unit fields, *i. e.*, one volt per cm.	
	Positive	Negative
Air.............	1.35	1.83
Hydrogen........	6.1	7.8

For practical purposes the relations of these mobilities to their corresponding fields of strength may be assumed to be linear for the time being.

Correspondingly, all non-conduction must be due to one of two things,—the non-movement of all ions and electrons present or their total absence. Materials through which ions or electrons can be moved freely are designated as conductors. Materials through which ions and electrons can not be moved are designated as true insulators.

With the new understanding of electrical phenomena, it is helpful to distinguish three sorts of conductors and corresponding conductions:

I. Metallic conduction—due to the free movement of electrons from atom to atom, requiring no e. m. f. for their detachment and only that e. m. f. which is required to supply the heat absorbed through the increased atomic agitation that has been produced.

II. Electrolytic conduction—the free movement of ions through an ionized liquid (or salt solution) from anode to cathode and vice versa, using an e. m. f., part of which is consumed positively or negatively in detaching or attaching ions at the electrodes in dissociation and recombination of the electrolyte and for the rest in supplying the inevitable heat due to the increased mechanical molecular agitation.

III. The movement of free ions or electrons in a non-ionized fluid. Conduction of this type is dependent upon two factors: (1) A requisite source of ions or electrons, and (2) the e. m. f. required to overcome the counter e. m. f. of space charges and again to supply the inevitable heat.

Fluid conduction may be set up in every kind of fluid, liquid or gaseous. No fluid of any sort pervaded with a supply of ions or electrons can properly be regarded as an insulator. Correspondingly every fluid in which ions and electrons are absent must function as an insulator.

Amorphous bodies or the precooled liquids, such as glass, the matrix of porcelain, fused quartz, etc., should be remembered as belonging to fluid conductors. The hardness of these bodies is due to their high viscosities, occurring when they were cooled from the molten state without crystallization. Pure, normal sulphur is an example of a non-fluid or crystalline body free of ions that intercepts completely the flow of ions and electrons, and functions, therefore, virtually as a perfect insulator. Fluids can have no such dependable barrier quality. This is the great reason why fluid insulators must always be supplemented with substantial barriers that break up the threadlike channels occupied by moving ions when driven by applied e. m. f.

Many have a feeling that air is a well-nigh perfect insulator or barrier to the passage of current forced along by applied voltage. The fact is that air has little or no barrier quality. If ions are liberated into the air, as by the passage of X-rays, on the application of a few volts only, the air may be observed to conduct with relative facility. It is actually no insulator in the sense that sulphur is. The great reason why air appears to function as an insulator in all ordinary cases is because of the absence of virtually all facility for liberating ions or electrons into the air.[8] To detach an electron from a metal electrode into a gas requires an electrical field terminating on the wall of the electrode that has been formed by the application of a million volts per centimeter. Above such voltage gradient terminating upon a conductor, air ceases to function as an insulator because the applied e. m. f. is sufficient to expel ions copiously from the one metal electrode and drive them through the air to contact with the opposing electrode where they are discharged, thus completing the electric current circuit. At correspondingly lower voltages, the air will function as an insulator only because electrons can not escape from the conductor walls.

Because metals and carbon when raised to sufficiently high temperatures will radiate electrons and thus supply ions copiously, air in the presence of highly heated electrodes ceases to be an insulator and functions abundantly as a conducting medium.

We are thus compelled to recognize once for all that actually air and other gases are not really insulators; the thing that did the insulating, which was mistakenly attributed to the air, was actually a property of the wall of the conductor-electrodes by which electrons were confined within the conductor and not permitted

to escape into the air or other gases occupying the space between and surrounding the electrodes.

It is particularly in this "no-man's-land" of ions and electrons, wherein insulators are not insulators and conductors are not conductors, that the electrical engineer is much concerned today.

The most important of the expedients for liberating electrons are:

I. From metal electrodes immersed in air or other gases

a. by heating the electrodes,

b. by applying ultraviolet light to the electrodes, for which some metals are more effective than others,

c. by coating the electrodes with certain salts that emit electrons copiously when heated,

d. by intense electric charges, 1000 kv. per cm. in air—1250 kv. per cm. in vacuum,

e. by evaporation or boiling of the metal or carbon electrodes.

II. From gases:

a. by exposing the gases to X-rays or by the emanations from radium and other radioactive substances,

b. by collision ionization, commonly called corona.

III. From metals to fluids

Electrons pass out from the cathodes and into the anodes immersed in electrolytes by the phenomenon known as electrolysis, long since well understood through the activities of the chemist.

IV. From metals to solids

Herein little is known as yet. There appears to exist no general understanding of the phenomenon of the passage of electrons from a metal to a non-conducting solid. Nevertheless, among the classical experiments of a century ago there was the one in which the metallic coatings of a "Leyden jar" were made removable. With the electrodes mounted the jar was charged. The coatings were then removed and the jar and coatings were examined to determine the seat of the charge. The coatings were discharged and replaced and the jar thereafter discharged as a whole, when it was found that the discharge was virtually as strong as if the coatings had not been removed, discharged and remounted. Through the new knowledge, we now know that when metal electrodes make good contact with solid dielectrics, electrons pass easily from the metal electrode to the atoms of the contacting dielectric and vice versa. The conclusion is inevitable that the contact e. m. fs. between the metallic and dielectric walls are extraordinarily low, permitting the easy exit of the electrons from the negatively charged electrode to the adjacent dielectric, and conversely from the dielectric to the positively charged electrode. Because in solid dielectrics neither electrons nor charged atoms can migrate with any but the slightest degrees of freedom, the dielectric functions as a barrier; an excess of electrons in the superficial face of the dielectric under the cathode and the opposite condition under the anode occurs and develops until the counter e. m. fs. of the bound charge thus produced balances the applied voltage whereon the action rests in a potential state.

V. Liberation of ions and electrons is produced by friction, splashing of liquids and bubbling of gases through liquids.

Of the highest importance, likewise, are the facilities available for the quantitative observation of the causes and corresponding effects of the activities of ions and electrons. In occasional circumstances, the quantities to be measured are all suitably large, including the expenditures of power for which there is at hand a wealth of well-known measuring expediencies. Often, however, one or more of the essentials to be measured are relatively very small or very large and the corresponding facilities available are as yet few, if at all, and general experience in their use may be lacking.

For the detection and gaging of small free charges in the air and gases, the gold-leaf electroscope, the delicate electrometer or galvanometer are often necessary. New uses for the old expedient of the potential plate or potential electrode are being found for the determination of potentials due to position, potential gradients, voltage duties, and potentials as modified by the presence of space charges. Conducting or non-conducting barriers in plates, tubes or other forms as required to limit the migrations of ions or electrons are often most helpful. A metal woven mesh, coarse or fine, may have its uses as a kind of "grid" for high voltage studies of the migrations of the electric carriers in air, gases, and liquids. The modern cathode-ray oscillograph and electron jet recorder are of extraordinary value for the promulgation of these studies.

In many studies the time-relation wherein a thing happens within the duration of a cycle or transient is of dominating importance. In these cases some dependable criterion in time relation must be found. When the actuating voltage is cyclic or transient and maintained with the requisite power, the non-inductive, non-capacitive resistor for "tapping out" fractional replicas of the total actuating voltage is a valuable expedient herewith. The potential plate, judiciously used, is also a helpful expedient for the same purpose.

Studies of this character in one way or another require electric power supply-sources in almost every thinkable voltage-current-time relation. Herein for continuous high voltages the old electrostatic machine and modern kenotron (the latter with requisite accessories) are available. Below and above commercial frequencies, laboratory forms of alternators and arc-converter and electron-tube oscillators are available; the choice must be determined by the special circumstances.

In the aggregate, there must be provision for the use of almost every character of substance occupying the immediate space about the electrodes which in turn must be available in every required form taken with

respect to the method by which ions or electrons are to be detached from them. Among these electrodes there must be those which are made of boiling metals or carbon.

Henceforth, problems without number will come up for attention in the electrical fields the solution of which will be feasible only through the use of abundant knowledge of ions and electrons to be acquired only by orderly, persistent effort. In closing, by way of example herein, one may mention the problem of the reduction of the damage done by power line flashovers. In a considerable percentage of these flashovers the trouble is started by indirect lightning, or other forms of over-voltages or some sort of attenuated conducting material laid across the circuit, usually from conductor to tower. In a great many of these cases the trouble is known to have had a very small beginning that now and then is not augmented and clears itself. But in the majority of cases the local metal faces of the conductor and tower are heated with great rapidity to the boiling point in those spots that happen to be located at the termini of the thin ion-electron stream that inaugurated the action. The ionized vapor liberated by the boiling that ensues enormously augments the conductivity of the original stream of electric carriers, resulting in the rapid development of a heavy short. An effective procedure for the solution of the problem may be to cover the conductors at the towers suitably with a heat resisting barrier that will not permit the discharge to terminate on the conductor in a sufficiently narrow spot to produce boiling so as to permit the action to clear itself. It is not forgotten that in procedures of this sort not one but all perceivable options that promise a solution must be worked through at least to that point from which it is seen that they may or may not be given up effectively.

In conclusion, it should be helpful to all electrical engineers to acquire a knowledge of the more important factors in the behavior of ions and electrons; and for the maintenance of a well-balanced progress in the electrical industries, it is highly necessary that some of the electrical engineers acquire, augment, and apply the highest attainable knowledge of this subject.

Discussion

R. W. Sorensen: Professor Ryan says, "There are two varieties of electrons, positive and negative." On this he can find much authority; in fact in his book, "The Electron," Dr. Millikan speaks of positive and negative electrons, but I much prefer in this particular to follow the practise of those who define the electron by saying it is a cathode particle such as is found in the cathode rays. I choose this path of thinking about electrons because we all know something about cathode rays. These rays have been found to be made up of negatively charged particles, and the particles are called electrons.

This definition makes the electron a single individual, always negative, rather than twins, one positive and one negative, and it is, as a consequence, more easily recognized. If the electron cannot be a twin, we must provide it with an affinity from which it wishes never to be separated, and in this form of nomenclature the term proton has been applied to the same individual that Professor Ryan has called the positive electron.

More frequently than not, these electrons and their protons are found in large groups, but, in the case of the hydrogen atom, they are alone, this atom being made up of one electron and a single proton nucleus. That points out one question to which we might refer in Professor Ryan's paper where he stated, I believe, that the positive electrons were not found alone; but this is the one exception. If one of these hydrogen atoms encounters a disturbing influence, such as an electric field powerful enough to detach an electron, the electron becomes free and there is left the single proton.

Proceeding in the direction of complexity of structure, we could discuss the helium atom which has two electrons attached to a nucleus that appears to have four protons.

When one or more of these electrons or negative particles is taken away from an atom, the remainder behaves in such a way as to indicate that it has a positive charge, and is known as a positive ion. Thus atoms become ions when they have a deficiency or excess of electrons.

I see no reason why protons as defined cannot exist in a free state in a hydrogen arc, but it is, of course, true that compared to the number of times one can find free electrons, such an occurrence is very limited.

I had planned to question the statement that "under all ordinary conditions approaching quiescence, free electrons adhere to atoms, otherwise neutral." But now, although a number of physicists think they are free, I am inclined to think that we shall get into less trouble if we take Professor Ryan's statement that these electrons are likely to attach themselves to neutral atoms, making them negative ions.

Something is said about electron travel. In regard to that, when we measure an electric current as so many amperes we are measuring the sum of the positive and negative ions passing through the ammeter.

I should like to suggest that perhaps as engineers we would clear up Professor Ryan's statements as to the movement of electrons by saying that the electrons or ions may be moved mechanically, electrically or magnetically; that is, you can move them by mechanical means by placing them in what we call electrostatic field, or in a magnetic field. I know that is exactly what Professor Ryan intends to say, but I think it would be better to say magnetically rather than electromagnetically.

On the second page Professor Ryan has divided conduction into three groups. I think we should add something to these. An electric current made up of these ions or electrons will also travel through a vacuum, and I do not believe that this has been included in these three sections. Also, I am not quite sure that these three groups as listed show conduction through an arc.

To the paragraph at the top of the second column on the second page I am inclined to add the idea that every atom has electrons; therefore, how can one have a fluid which does not have atoms and hence does not have electrons? Correspondingly how would it be an insulator under Professor Ryan's definition?

Considering practical engineering application, I am one of the many who have a feeling that air, pure and unadulterated, if not a nearly perfect insulator, is at least a pretty good one and one which will serve us for a long time. In the final analysis, all our transmission lines are air-insulated, the porcelain bead chains with which we decorate our transmission towers being, after all, only decorative suspenders which serve to keep the lines from falling. The insulator is the air.

I think the reason Professor Ryan and I differ in this is because he says a thing is not a thing unless it is at least 99.44 per cent pure. Air, then, is an insulator just as oil is an insulator. If we introduce into the air, free electrons or ions, the air as an insulator becomes defective in exact proportion to the amount of impurity introduced. In undertaking our engineering problems we call oil an insulator. It never is a perfect one and it ceases to be an insulator at all if moisture is added to it, its value as an insulator decreasing in proportion to the amount of water added.

I might also add that in the sense which Professor Ryan has spoken of an insulator, a vacuum is not an insulator. Current can and will go through it. To my way of thinking, a high vacuum is an insulator, but it is not a perfect insulator; therefore, Professor Ryan says it is not an insulator.

When two conductors are brought very close together, a potential of 1,000,000 volts. per cm. or even greater potentials may be required to break down the gap. Also, cold electrodes in high vacuum require potential gradients of this magnitude as ionizing potentials, but charged electric conductors in air at sea level and separated practical distances will arc over one to the other if the potential gradient in the air between them is 30,000 volts per cm.

However, on this point I must assure you that though we are using different words, Professor Ryan and I understand each other thoroughly in this matter, and in conducting experiments involving these things, we would use in many cases the same strategy and anticipate the same results.

C. E. Magnusson: There is one factor—in fact a vital factor in the electron theory—the physical characteristics of which are seldom discussed while the attention is focused on the several forms of mass units involved. I refer to the electric charge. What is the innate nature of positive and negative charges, which take possession of, or are possessed by, electrons, ions, protons, corpuscles, or by whatever name the mass units may be designated? How can the charge, if located on or attached to an electron or other mass unit of definite size, produce action at a distance or be attracted or repelled by other charges attached to far away mass units? What is back of Faraday's lines or tubes of force? May I ask Professor Ryan to give us his concept of the electric charge?

C. L. Fortescue: I think one of the reasons why electrical engineers have difficulty in following and applying the electron theories is because it is the first time they have come up against the subject of statistical mechanics, a subject with which physicists have become very familiar in their study of the dynamic theory of gases.

Now many laws of physics, dynamics, and physical chemistry were found before the kinetic theory of gases was well established, and these laws prove to be true under practical conditions.

Electrical engineers have been accustomed to think of air as an insulator which breaks down, under ordinary conditions, at about 30,000 volts per cm. This, of course, is a very convenient way of looking at it, but we know by the electron theory that this isn't at all true except under certain specific conditions.

The electron theorists tell us that the air will break down at any point where the rate of ionization and the rate of recombination are equal. I believe the rate of recombination depends upon the mobility and the rate of ionization depends upon the density of the air and also upon the total value of applied potential or the difference of potential between electrodes; but we have two quantities there that have to be taken into account. As a consequence we find for a very small separation, as Mr. Sorensen points out, a breakdown strength of the order of 1,000,000 volts per cm. In a larger space the breakdown strength of the air becomes less and less. In the ordinary spaces the engineer uses, we find it averages around 30,000 volts per cm.

In Professor Ryan's paper, I was a little disappointed when I read his remarks about the three sorts of insulators. Unfortunately we are likely to generalize and think of these things practically as hindering our methods of insulation. For instance, Professor Ryan makes his statement in such a way that one would think, reading it superficially, that barriers were absolutely indispensable in connection with all insulators. We know by actual experience if proper care is taken to prevent the formation of corona, or, putting it in terms of the electron theory, when local ionization is avoided, we can use air without applying barriers, and the strength of the air will follow the avarage law which I have mentioned, breakdown taking place at about 30,000 volts per cm.

Certain conditions occur when the bounding surface between solid dielectric and air apparently does not follow the law of breakdown in air. I think these discrepancies have been attributed to the effect of the absorption of gases or moisture on the surface, but if you have a perfectly clean surface of proper conformation, the path along the surface will have the same breakdown strength as the air has.

I should like to ask Professor Ryan to clear up this difficulty in the interpretation of this paper. We are sure as engineers that the air is still a medium for insulation.

F. G. Baum: For many years (since 1911) Dr. Ryan has exhorted us to study the electron. I am here as a missionary today to try to help show the importance of studying the electron. For many years the subject of electrostatics has been taught in schools. In my opinion, there is no such subject as electrostatics except as you get down to an extreme vacuum where you have no ions injected into the vacuum; otherwise you have "electron mechanics," and I believe in a very short time you will find that our textbooks will be rewritten and the term "electrostatics" practically eliminated. It is wrong and we must get another proper term and realize that we are dealing with objects moving at very high speed and causing entirely different conditions from those which we thought true when we studied electrostatics.

Ordinarily, we take two bodies and draw lines between and say that is an electrostatic field. It is an electrostatic field only because electrons are moving from one of those bodies to the other; and our higher voltage insulation problem is dependent on a knowledge of handling this electron flow.

H. J. Ryan: Replying to Professor Sorensen: I can accept, if necessary, the use of *proton* in lieu of *positive electron* as proposed by some physicists. It is simply a choice of terms. Personally, however, I like Doctor Millikan's use of *positive electron* to emphasize the fact that all matter is substantially made up of cathode and anode particles. As implied, it is true that experimental facilities are as yet more abundant or convenient for the liberation of cathode particles than for anode

particles. These cathode and anode particles surely are twins of just the character referred to. They carry elemental charges equal in amount and opposite in sign. The positive electron or proton is much smaller in diameter and has a correspondingly greater mass than the negative electron. The same elementary electric field or charge centers in the electron whether positive or negative,—the one and only known difference being that of direction or polarity. I do not feel that the use of the term "proton" is adapted to the presentation of these facts as well as the term "positive electron." It is helpful to have been reminded of the stripped hydrogen atom which can be produced and which must behave as an isolated positive electron, proton, or anode particle as we may variously call it.

I quite agree with the idea put forth in regard to the movement of ions and electrons mechanically, electrically or magnetically. However, it should be remembered that they may be moved also by any combination of these agencies. For example, ions in the air that is blown along between the poles of a magnet and between metal plates maintained at a difference of potential will be moved mechanically, magnetically, and electrically. It may be that it is not helpful to compound these terms and say that the ions were moved electromagnetomechanically. I am quite agreed to say that they were moved electrically, magnetically, and mechanically.

I am glad to accept *vacuum* for a place in the list of electrical conductors. I had left it out originally because in the first place a vacuum is not anything, anyway in the ordinary sense, and therefore can not assist or hinder the migration of ions or electrons; in the second place, as Mr. Wood brought out in the talk referred to, as soon as ions or electrons are admitted to the vacuum it may in a sense be thought of as having ceased to be a vacuum.

I can see no difficulty with the statement "No fluid of any sort pervaded with a supply of ions or electrons can properly be regarded as an insulator. Correspondingly, every fluid in which ions and electrons are absent must function as an insulator." Of course, each molecule of neutral transformer oil is made up of complete or neutral atoms that in turn are made up each of an equal number of positive and negative electrons bound together, forming neutral aggregates. Such oil is not a supply of ions and will not conduct under an impressed electromotive force of moderate value. If, however, the oil contains impure water in suspension it is pervaded with a supply of ions and will conduct.

I cordially admit the powerful revulsion of feeling that must come to one when first confronted by the fact that it is the wall of the metallic conductor when immersed in air that is really the insulator and not the air. Take away the air, as one may do in a vacuum, and the conductor will be insulated just as well as before. This is the fact that made me doubt the wisdom of putting "vacuum" in the list of conductors. It does not really matter, though, as long as we can agree as to the circumstances in which it does or does not conduct. Years ago, when the idea prevailed in my own mind that air is one of our best insulators, with dielectric strength greatly enhanced by compression, I undertook to provide a powerful dielectric by means of air compressed to 1500 lb. per sq. in. I was greatly perplexed by the results because I was wholly unaware of the fact that air will permit ions to pass through it freely if one will but provide a source thereof, such for example as a hot carbon electrode. We did not know then, as we know now, that in all ordinary circumstances electrons cannot escape from the wall of a conductor which is the basic reason why we were made to believe that the air was the real insulator. Furthermore, we did not know then, as we do now, that at extraordinarily high electric intensities at the surface of an electrode conductor (1,000 kv. per cm. approximately) electrons or ions will escape from the wall of the conductor and be driven freely through the air to the opposing electrode where they will be discharged. With a knowledge of these facts twenty years ago we would not have been perplexed by the anomalous behavior of air as an insulator when put to a real test.

I cannot agree that it is a matter of degree to be covered by such a small item as the departure of 99.44 from 100. It is not a question of purity or impurity any more than it is in the case of water. Water will conduct as long as it has ions suspended in it. Being a fluid it ceases to conduct only when the supply of ions has been eliminated. And this will cover also the reference to oil.

Doctor Magnusson asks the question "What is the innate nature of positive and negative charges which take possession of or are possessed by electrons, ions, protons, corpuscles, or by whatever name the mass-units may be designated?" This question and the form in which it is put are helpful even if one has not a ghost of an answer. I can only discuss this question; I cannot begin to answer it. I can only offer what appears to me to be a reasonable conjecture in regard to the perhaps most important attribute of the electron. This is that all electric fields are made up of unit-fragments alike in constitution. Each field fragment terminates on an electron from which it extends radially and expands uniformly, and so far as we know, indefinitely. These field fragments are the same, whether positive or negative, differing only in polarity and in radius of the electron surface at which the field terminates, being much smaller for the positive electron which must, therefore, have a correspondingly greater mass, the measure of the energy that was used in the extra concentration of the field. Whatever else they may be, electrons are surely these field fragments. All greater electric fields are merely aggregations of these unit-field fragments. The electric intensity through any field volume is the vector sum of the radial field fragments attached to the electrons that constitute the charges to which the field is attached. Maxwell understood the composition and resolution of electric fields and taught us to locate "tubes" of electric force by drawing diagonals through the parallelograms that are formed by the radial lines which represent the electric fields that extend uniformly in all directions from charges located at a point. It is the vector composition of superimposed fields terminating upon the positive and negative electrons that forms the "tubes of force" of an electric field. It is in the presentation of these facts that I find the term *positive electron* more helpful than *proton*.

It is also helpful to have Mr. Fortescue emphasize the importance of *statistical mechanics*. I trust that all who are interested in the new knowledge will read thoughtfully what he has said. He also refers to the extremely short space that must exist between metal electrode faces before electrons will leave them and the vacuum, or gas-filled space between them, will become conductive. If the fact is allowed to stand in that light I fear we shall give our more general audience the impression that this action is the result mainly due to the close proximity of the metal electrode-faces. In fact it cannot primarily be due to the nearness of such faces as Hayden and Steinmetz have shown in their A. I. E. E. paper on the dielectric strength of the vacuum.[2] The preparation of my paper was only possible by the use of old terms with new or modified meanings. I had to count, therefore, upon precisely such disappointment as that of Mr. Fortescue because I have referred to air as a conductor instead of as an insulator. I have no thought of proposing that we stop calling air an insulator. What I do want to see established is a better understanding as to how it can be made to conduct abundantly. With that, and with more of a background in the subject which will come with experience, the choice of terms with no doubts on important difference, will be readily accomplished. I am a hearty advocate of the high

2. High-Voltage Insulation, by J. L. R. Hayden and C. P. Steinmetz, A. I. E. E., TRANSACTIONS, 1923, page 1029.

value of the *Fortescue principle* wherein air insulation barriers of powerful solid dielectrics are applied, having boundaries coincident with those of the tubes of electric force in the air adjacent. Such barriers displace the air in regions of dense electric fields that would otherwise ionize and afford prolific conduction. We do not differ as to the facts and in the end we shall have put new meaning into old terms or adopted new terms by which all who use them will apply helpfully the new knowledge of these things.

Mr. Baum has declared rightly that electrostatics are hopelessly inadequate for understanding and for effective control of electrical states and actions. This I know to be the case even though we cannot agree as to facts when he says that a quiescent electric field between two charged bodies is such "because electrons are moving from one of these bodies to the other." Of course, this brings us face to face with the age-long problem of "action at a distance" and my question to myself is: "Has Mr. Baum made some progress toward the definition and solution of that problem?" Most of us have not,—we face a high wall and cannot see what is beyond. To me the static electric field between two bodies is the composition of the two field aggregates of opposing polarity that terminate on the corresponding free positive and negative electrons that are bound to the surfaces of such bodies.

Engineering Research—An Essential Factor in Engineering Education

BY C. EDWARD MAGNUSSON[1]

Fellow, A. I. E. E.

IT may seem trite to assert the interdependence of engineering research and engineering education, and no doubt most workers in the vineyard would consider the title of this paper as axiomatic,—the statement of a self-evident fact. *In theory* the great majority of the members of our engineering faculties, as well as practising engineers, who have given time and thought to the training of young men for the engineering profession, readily subscribe to statements emphasizing the importance of research as a factor in engineering education; but *in practise*—well, "the spirit is willing but the flesh is weak."

In the majority of our engineering colleges and technical schools very little if any research is in progress, and even in our leading institutions comparatively few members of the teaching staffs are actively engaged in worth-while investigations. As yet the research spirit is an attribute of individual members of the faculties and not of our engineering colleges as institutions. Professors who have gained recognition as investigators are looked upon as ornaments, and not as the bone and marrow of the university. Research remains a side issue, something very desirable and highly creditable to our technologic institutions, but not to be taken seriously as an essential factor in the training of engineering students.

The rapidly increasing importance of engineering research in the industries stands in striking contrast to the apathetic condition that exists in many of our educational institutions. In large manufacturing concerns the research departments have gained in recent years prestige and influence far beyond the fondest dreams of the pioneering investigators of thirty or forty years ago. The development of new ideas is by now an integral, and, in many cases, a vital part of industrial organizations. Research engineers are continually transforming new ideas into effective weapons of offense and defense in present day industrial warfare. The research departments provide the means for gaining new markets, and form the bulwarks of defense against competition in established fields. That industrial research will continue to expand is certain, as the work rests on a sound economic basis. Properly conducted research not only pays well—in fact brings large returns on the investment—but is a basic necessity in order to enable industrial organizations to live and prosper.

While, in the main, the expansion of research in the industries has had a salutary effect on our engineering colleges, still it has developed conditions adverse to the effective training of engineering students. Industrial research has emphasized the importance of giving students clear concepts of well established fundamental principles and created a new and highly attractive professional field, thus providing the studious, scientifically inclined, engineering student with a better appreciation of fundamental physical laws and a definite goal for his ambition—to become a research engineer.

Of adverse factors two are of special significance:

1. The type of mind required for becoming a successful research engineer is essentially the same as for gaining prominence as a professor in some field of engineering. As industrial concerns are able to pay larger salaries than educational institutions, and what is often of greater importance, can provide better facilities for carrying on investigations, the teaching staffs are being robbed of their best men, and, to a large extent, have been cut off from the supply of desirable recruits. This factor affects not merely the faculties of engineering departments but likewise those of physics and chemistry. Unless this movement can be checked and emoluments of professors be made as good or better than those given to research engineers, the results will

1. Dean, College of Engineering, Director, Engineering Experiment Station, University of Washington.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 17-19, 1925.

soon prove disastrous to technologic training. For, in order to have a first class college of engineering, there must be first class men on the faculty.

2. Even under present conditions, the amount of research accomplished by industrial concerns is overwhelmingly greater than what is done in the universities and professional schools. With industrial research staffs having several thousand members—as, for example, the recently organized Bell Telephone Laboratories—and with adequate facilities at their disposal, is there any wonder that the research output of a college faculty, with its members giving practically all their time and effort to teaching, should be very small in comparison? The contents of our scientific and technical journals and the proceedings and transactions of our scientific and technical societies give evidence of the increasing preponderance of papers from industrial research departments, with a corresponding relative decrease in contributions from educational institutions. To those who are familiar with existing conditions for conducting research in our colleges of engineering and institutes of technology, as compared with the facilities provided by research departments of many industrial concerns, the wonder is not how little, but how surprisingly much, the professors actually accomplish.

Still the distressing fact remains that the relative importance of our institutions of learning as centers of research is rapidly decreasing, a situation that should be given serious consideration, not only by faculty members of our engineering colleges and technical schools, but likewise by all progressive engineers and captains of industry. It is, by now, quite generally recognized that during his four years in college, the main purpose of the prospective engineer is to acquire a mastery of engineering fundamentals and a working knowledge of mathematics and English, while comparatively little importance is attached to the gathering of detailed information on current practise. (In paranthesis it may be noted that while engineers and educators are generally agreed that the major part of the student's time and effort should be given to engineering fundamentals, there are apparently widely divergent views as to what the term implies. For the purpose of this paper let it be assumed that by *engineering fundamentals* is understood the *basic physical laws* with and under which the practising engineer works, lives, and has his being.) The student in college should gain a deep and full realization of the far reaching importance of the principle of the conservation of energy, Newton's, Joules', Ohm's and Kirchoff's laws, and similar established basic physical relations, and *acquire the ability to apply them correctly to quantitative engineering problems.*

In order to give the student a clear insight into the basic laws of engineering and their application to quantitative problems with that perspective of coming events, so tersely expressed by Mr. B. G. Lamme, "*it should be remembered that much of what these young men will work with has not yet been discovered*" and requires teachers who are continuously applying basic principles in their own search for new truths. The title "research professor," which, in the last few years, has made its appearance in several university catalogues and bulletins, indicates an unfortunate tendency. It gives official recognition to a separation of the teachers from the investigators—and thereby erects a new barrier between the students and the progressive thinkers on the teaching staffs. It would be better both for the students and institutions if successful research could be made a requirement for all members of the faculty, and that in rating our engineering colleges and technical schools, more emphasis could be placed on the quality and number of engineering bulletins and scientific papers published than on the number of students or available laboratory equipment and size of buildings. There can be no question that much more research must be done in our engineering colleges than obtains at present. Attempting to solve new problems is the best means for developing initiative and the ability to think.

If it be admitted that research surroundings are essential to the proper training of engineering students, and that present conditions in most engineering and technical schools make worthwhile investigations well nigh impossible, it is evident that the question of improving existing conditions must be given serious consideration.

Of course most of the difficulties that beset our engineering colleges would be eliminated if adequate funds were available for research facilities and pay for staff members comparable to those provided by industrial organizations; but there is little hope for general relief in this direction, as the number of students seeking training is, in most institutions, increasing at a greater rate than the material wherewithal. As a more likely method for bringing engineering students in touch with worthwhile investigations, the author would stress the importance of a closer and more extensive cooperation between the research divisions of industrial organizations and educational institutions. The following suggestions are submitted:

1. Industrial organizations should establish numerous *research fellowships in engineering colleges*, not as gratuities but as necessary investments against their own future need of properly trained additions to their staffs.

2. *Cooperative work between research departments of industrial organizations and educational institutions* should be greatly increased.

3. Some form of *bonus system* should be established by which engineering colleges would receive financial returns from industrial organizations for having discovered and trained exceptionally successful engineers.

4. Let educational institutions take out *patents on new ideas of commercial value* originated by faculty members; that is, expand and make effective the plan recently adopted by Columbia University.

5. Establish research foundations as integral parts of engineering colleges.

6. Let a larger share of the normal income of educational institutions be expended on investigational work. This would be in accord with the policy adopted by industrial organizations. Twenty or thirty years ago the budgets for research were insignificant in most of our industrial organizations, while today the research divisions in several manufacturing and operating companies expend millions of dollars annually.

7. There should be instituted an *exchange of engineers* between engineering faculties and engineering staffs of manufacturing companies and other industrial organizations; the plan might be somewhat similar to the *exchange of professors* between European and American universities. If a man for man exchange could not be effected, let the manufacturing companies donate the services (Sabbatical year) of some of their engineers, who would devote all of their time in selected engineering schools during a full academic year.

To properly train engineers is an expensive process. To obtain satisfactory results our engineering colleges must be provided with much *greater financial support* in the future than has been the case in the past. If the service rendered by our engineering colleges is of value to industrial development, let organized industries assist in providing adequate means so that the work may be well done.

If the basic necessity for research on a scale larger than hitherto exercised in our engineering colleges and technical schools is fully understood and appreciated, means and methods for improving existing conditions will no doubt be forthcoming.

Discussion

L. N. Robinson: Professor Magnusson emphasizes the point that engineering courses should teach students to think if nothing more. If that is so, why do not engineering curriculums, in general, include courses in the mental sciences, particularly logic and allied subjects? However, it is not my present purpose to argue for or against the inclusion of any particular subject in the curriculums. What should be pointed out is that present conditions indicate a general lack of scientific treatment in the design of engineering curriculums as well as in their application.

We insist that scientific methods should be employed in designing engineering structures. Engineering students have an equal right to insist that scientific methods be employed in designing the curriculums of engineering schools.

When electric generating stations are designed by the same methods that are employed in laying out many engineering school courses, hybrid plants are produced in about the same proportion as our engineering schools turn out bond and automobile salesmen.

In designing an engineering structure, it is customary to decide first what is to be designed,—whether it shall be a bridge, an office building, a locomotive or something else. Next we determine which parts shall be of steel, which of copper, etc., then we prescribe methods of fabrication and assembly. In other words, every step from the inception of the enterprise to the finished product is worked out with utmost scientific care.

Is this method followed in designing engineering curriculums and in training engineers? Before it can be said that engineering courses, themselves, are scientifically designed, we should at least first determine what the product of an engineering course should be. Then the elements that should constitute the course can readily be determined, with equal care to deciding how the courses shall be conducted.

Last June at a commencement the chancellor of a university said that the world is full of people who know all about education except what it is for. This is a challenge to the engineering fraternity and to the engineering schools in particular; it demands a scientifically sound justification for our college courses and especially for our engineering courses. And, since we profess to be scientific in our engineering work, we should be better able than the humanists to answer the challenge. In doing so, however, we must be especially careful not to mistake consensus of opinion for sound scientific truth else we shall class ourselves with those who scoffed at Christopher Columbus because his views differed from generally accepted notions.

J. C. Clark: It seems to me that Professor Magnusson has lost a grand opportunity in his paper to bring out one of the main reasons why we should have research in engineering colleges. He has stressed the value of the educational aspect of research almost exclusively, and has pointed out that it nearly goes without saying that research has an indispensable part in technical education. Professor Sorensen also emphasized very strongly the educational value of research in the colleges. In other words, it is for the good of the colleges and the students that research is carried on in the colleges.

I believe that it ought to be pointed out by Professor Magnusson that the industry needs engineering research in the colleges as much, if not more, than do the colleges. As Professor Magnusson has so emphatically stated, it is true that the large corporations of today have millions to spend in research. They have large and well trained staffs to carry on industrial research, and they carry it on successfully and efficiently. On the other hand a great many of the smaller concerns have very meager appropriations with which to work and carry on research.

It follows that most of us very much need to have a place to have scientific facts revealed. Not only is this true in the smaller manufacturing industries, but it is even more vital for the public to have these independent public laboratories of research which the colleges and universities can so well maintain. It really is not so much the amount of work done that matters, as it is the unbiased check that such laboratories can give upon the results that are revealed and published by the larger corporations.

We do not charge that the large corporations color what they print about their laboratory results, but it is human and almost inevitable that they show the best side of what they find out, and somewhat neglect the unfavorable aspects of those things they are trying to promote.

By doing a very little work sometimes with small funds, the smaller college laboratories can aid industry and the social body a great deal. The exact amount of money at their disposal is not of prime importance although it is true that they need a vastly greater support than they now have.

The professor who has one thousand dollars a year to spend for all his equipment, including its repair, and maintenance, is so handicapped that he can surely do but little with the energy that he puts into the work.

I should endorse what Professor Magnusson said: Industrial establishments of any size that do no research have "signed up for the exit." However, industrial research in smaller establishments may not be carried on because they have not the facilities, and thus they have to depend upon the colleges.

I find much in Professor Sorensen's paper which is of interest. Professor Sorensen starts out with an assumption which surely needs no argument,—that research and engineering are insepa-

rable. Research *must be* a part of engineering education. He takes the same attitude as Professor Magnusson does in pointing out the necessity for it from the standpoint of education. This is self-evident indeed.

Professor Sorensen gives the time honored definition of engineering that I believe was given by Tredgold, the first President of the Institution of Civil Engineers in England; "The art of directing the great sources of power and nature for the use and convenience of man," etc., running through many, many words. It starts as a catalogue of the functions of engineers and thus its weakness is obvious. It can, of course, only begin to catalogue the functions of engineers, but I think that in this very definition, a part of the weakness of modern engineering education lies. Educators and engineers have been more or less hypnotized by such definitions of engineering, emphasis being placed entirely upon the technical aspect of engineering, the scientific, and the big and glorious things to be done by engineers.

I should substitute a very much shorter definition for engineering. I define an engineer as one who directs the economic use of matter or energy. I should let it go at that because I believe that we have among us as great engineers who are directing the destinies of banks or steamship companies, from the standpoint of executive officers, as we have in any other capacity. In other words, technique should not be stressed exclusively in the work that is done in the colleges. There should be a little more emphasis placed on economics. There are very few colleges today that devote any great amount of time to the study of engineering economics. I do not see how it is possible to turn out men with a proper attitude toward engineering without giving them much study of the principles of engineering economics, not the old social economics, but the engineering student does need a very considerable amount of engineering economics if he ever becomes a true engineer.

I wonder how much deleterious effect this long-drawn-out definition of Tredgold's has had upon engineering education. Has it not hypnotized the profession somewhat into thinking too much about the imparting of information about technical things, perhaps information about the things that can best be learned by the man after he is out of college?

In Professor Sorensen's paper I found one thing with which I think many men in practical research would particularly take issue. That is the standpoint that the undergraduates' thesis was wisely eliminated. Professor Sorensen says "it was therefore wisely eliminated." The very next sentence takes the curse off, "But we should not forget that the thesis is symbolical of research—a function which must be the keystone of engineering education if the engineer is to occupy the place for which he is ambitious."

I think that is certainly true. The thesis is needed to support the idea of research, to give some little practise in the methods of research, with the object of bringing out latent research talent in the student.

Professor Sorensen reveals that he has some such idea in a latter part of his paper, since he speaks of the honor sections that are established at Pasadena where the better men are permitted some chance to help in advanced and special work, assisting research men. I think he has there revealed his true attitude toward the research that may be done by undergraduates.

It seems to me that the practise of segregating the students into the ordinary and the extraordinary,—the latter class including these so-called honor men,—is one of the very best developments I have ever seen. I wonder if the real reason for eliminating the undergraduate thesis was not rather the difficulties that were encountered in lack of equipment or lack of time and energy for the administration of the theses than the lack of educational and developmental value in them?

In the paper by Dean Pender and the one by Professor Sorensen there are two quite distinct methods given for the selection of engineering student material. Of the two, I think the one that is the more hopeful is the one that is being tried out in Pennsylvania. The statement that Harold Pender made is quite true; that a boy fresh from high school is usually just a boy,—and I think it does require the few years of college which are a part of the Pennsylvania plan to bring out the judgment of a student and too, to weed out the defective material found among students. It is not defective material except that it is unfit for engineering although possibly very fit for some other, perhaps higher, walk of life. At any rate, there is a great difference among students in their fitness for engineering.

I am somewhat in doubt as to the real value of the physical examination in the Pasadena plan because we have in our electrical history so many able men who might have had difficulty in passing the Pasadena physical test. Is it not going to eliminate an occasional man who has great latent ability in analytical ways?

H. V. Carpenter: This matter of engineering education is one that we shall always talk about I suppose. The Society for the Promotion of Engineering Education is at the present time spending something like a hundred thousand dollars, and I don't know how many dollars' worth of time, in analyzing methods of engineering teaching.

It seems to me that one of the most difficult problems we have before us in that study is this matter of research. You remember that some Roman ruler said, "All right, if we destroy the Greek statuary, we shall send some men out and have it replaced." If we aren't careful, we shall put our research work on that same mechanical basis. I believe that a research man is born. Maybe Dean Magnusson can make a research man, but I am afraid I cannot. I think it is more a matter with us of being able to discover the research man when he comes along in our classes, rather than being able to take an entire class of students and turning them all into first-class research thinkers.

What we need to do is to teach these men to think, and research is only one of the better methods of teaching a man to think. A large share of these boys will never be research thinkers, but they will be very effective engineering thinkers in the ordinary sense of being able to go out and size up a job and put through the best design for it. They may not be research men, but they will be thoroughly useful men on straight engineering propositions.

It is our business to give the man who can do original thinking the inspiration to go ahead to develop his abilities in that line, and to give him a chance in the laboratory. Professor Sorensen's scheme is a very good one; they have adopted a similar one at the Massachusetts Institute of Technology where the honor men are to be given a chance to do as much as they please. The smaller institutions have always done that to a considerable degree in an easier way, having a much simpler problem.

Dropping the thesis was a good thing, I think. I agree with Professor Sorensen on that as a requirement for every student, but for the student who shows interest, I think the thesis should be maintained, and carefully nursed along. We cannot expect revolutionary things from the senior, but perhaps if we start a real genius to thinking he may turn out a revolutionary piece of work in later years.

L. J. Corbett: Doctor Magnussen describes the tendency to take research away from the colleges. I think we need not fear for that, as times are changing. As he states, the large companies are doing a great deal of research, but there is another factor; they also need men—and one of the ways to develop men is through this very research work. I believe this is being recognized by some of our large companies, as evidenced by the assistance which has been given recently, to both the California Institute of Technology and Leland Stanford, Jr., University, in the way of aid in the establishment of high-voltage laboratories. These, no doubt, will give a good account of themselves in con-

tributions to engineering research, and some students will recivee valuable training in this field.

From Mr. Sorensen's paper I note that they are omitting the engineering thesis at the institution he represents. However, from the discussion which took place, I see that there is still some opportunity given for the honor men to investigate along the lines of their special inclinations, thus recognizing work on such theses.

To return to Doctor Magnusson's paper, we must recognize the tendency of the companies of today to require specialization in their men. This, I think, has been the inference in the advice which has often been given to engineering colleges to have actual departments of research where some men of the staff could go ahead and do research only, without the change in mental attitude which is necessary when a man does some research and also teaches a group of undergraduates, old, well-known material.

I think the work of the teacher, as Professor Carpenter has stated, is inspirational. I think that if you can inspire a student to make the best use of his faculties, and not to consider his education complete when he has his degree, but to go ahead with his studies and research—you will do a greater work than merely filling him with information and making an encyclopedia of him. I think this quality is particularly exemplified in the man we have with us in the person of Professor Ryan. I believe that all his students will vouch for the inspirational quality of his work.

There is one feature in Dr. Pender's paper that struck a discordant note. In one of his conclusions there is the statement that the student should recognize that engineering is a profession, and not a job. That is all very well for us to recognize, but I think we should not emphasize it too strongly to the undergraduate student, because it is due to such thoughts that we have men who are reluctant to don overalls after getting their degrees. I think a man would get farther in the engineering profession if he were willing to don overalls for a time after his graduation and learn the rudiments of practical work.

J. S. Bates: I once heard an engineer defined as a man who is skilled in the use of the word "approximately." There is really a great deal in that because no matter to how many decimal places we carry our calculations, there is always one more; one or a vast multitude makes no difference. For that reason we should say a very important part of an engineer's education is to determine what percentage of error is to be allowed.

G. S. Smith: In the University of Washington we still have the thesis work scheduled as an elective but it has been virtually discarded, since it is seldom chosen by the student. However, I believe we have found other ways more effective in obtaining the results aimed for in the usual thesis work.

Several of our courses scheduled for upper classmen and graduates, are presented in such a manner that each student, or more often a group of two or three students, selects or is assigned some individual problem to be worked out completely. These problems are usually of such a nature that they require a considerable amount of thought, reference work, or experimental work, and thus arouse in the student any latent inclinations toward research work.

As an example I should like to mention a course to which we have paid a good deal of attention in our institution; that of electrical transients as a prescribed course of undergraduate study. In the laboratory part of this course a certain number of topics are assigned to the student for which he must obtain representative oscillograms. This is the more or less routine or practise part of the course. To satisfy the remainder of the requirements, the student must select some problem or topic, acceptable to the instructor, to be investigated by the taking of oscillograms. This problem must be one which has not been previously chosen by other students who have taken the course. Thus their work is, to a certain extent, original.

The response on the students' part is usually more than gratifying. They not only put more energy and thought into this part of the work than in the routine portion, but they also show a strong tendency to attack it from the investigational point of view; that is, they try to find the best method of attack, try to determine the results they expect, and then attempt to verify them experimentally, watching all the while for unexpected results. At times, of course, they make complete failures, but more often they are very successful.

H. H. Henline (communicated after adjournment): I wish to emphasize the importance of full and frank discussion of the problems of engineering education by members of engineering faculties as well as by executives in industry. These authors have pointed out some very serious defects which are found in many curriculums.

Most of the engineering curriculums now in effect were planned twenty or more years ago, and changes made since have not altered in any essential details the general plans followed originally. Therefore, we find that most of the curriculums furnish excellent preparation for certain types of work which some of the graduates enter. However, this number seems small when compared with the total. On account of the extremely rapid progress which has been made in many branches of engineering during the past few years, we find ourselves living in a period when the applications of engineering knowledge are so many and diversified in character that any curriculum designed to meet directly certain needs in industry may indeed prepare men in a most excellent manner for those needs, but it fails utterly to prepare them for the great range of engineering problems, both executive and technical, which all graduates will be called upon to solve.

There is a strong and growing tendency to choose executives from the men with engineering training, since the problems which executives in industry must meet are becoming so complex and so closely allied with fundamentals of engineering that great dependence must be placed on the judgment of engineers in order to reach the correct solution. Obviously the schools cannot train men directly for executive positions, since qualifications for such positions depend greatly upon inherent characteristics, and any amount of training would not make capable executives of men who do not possess the necessary characteristics. However, if we wish the engineering graduates who do possess such characteristics to have opportunity to enter the management side of engineering, we must give them the broad, general foundation so absolutely essential.

One of the most noticeable features in the large amount of discussion of curriculums occurring in recent years is the fact that many of our largest employers of technical graduates now wish to secure men who have had a broad training in general subjects and the fundamentals of engineering rather than men who have specialized in a particular branch of engineering. Thus we find that the old situation in which teachers wanted to adhere to fundamentals, and many executives in industry advocated certain specialized courses, is rapidly reversing. Now we find the leaders in industry not only frowning upon specialized courses, but even considering many courses as too highly specialized which are given with the excuse that they are necessary from the standpoint of fundamentals.

In the planning of an engineering curriculum, certain decisions must be made as to the types of activity for which it should prepare men. In the present stage of development it seems necessary to recognize the needs of two distinct groups of students. Those who expect to spend their lives in highly technical design or research must have a more extended technical preparation than those who will be engaged in commercial or industrial phases of engineering. Both groups need a broad foundation on such subjects as English, economics, biology, geology, history, business law, etc., and a thorough training in chemistry, physics, mathematics, mechanics and other subjects which make up the heart of engineering. Such training should

be mixed with, and followed by, courses giving the fundamentals of all of the principal branches of engineering, and there should be a reasonable amount of time available for elective subjects. Thus far there is no serious difference between the wishes of executives in industry and teachers of engineering. It, therefore, seems that the chief cause of argument is the relatively small group of men who will engage in research and other highly technical phases of engineering. This group must have better opportunities for the development of research ability and specialized study than can be provided in any four-year course which makes necessary the provisions for training in the fundamentals.

It seems that the best solution of the problem may be a four-year course following the general outline mentioned above and leading to some such degree as Bachelor of Arts or Bachelor of Science in Engineering. This curriculum should be so planned that students may have good opportunity to develop powers of initiative and judgment to the maximum extent, and to determine the kind of intellectual effort for which they are best qualified. In order that they may see how they can best fit into that field, it should give them a broad outlook and an excellent perspective of the whole engineering field. Graduates of such a curriculum would be prepared for commercial pursuits and for many types of technical work in which employers prefer that specialization be deferred until after the entry into industry. It is believed that they would advance more rapidly in either commercial or technical employment than if they had graduated from the narrower four-year engineering curriculum.

For those who wish to prepare for research and other highly technical branches of engineering, there should be provided pportunities for two years of graduate study. Having completed the liberal four-year curriculum, they would have the broad foundation which should precede advanced study. The graduate curriculum should be planned with the idea of developing ability in research and permitting specialization in analytical studies, design, or other branches of engineering. Since the number of students in the graduate classes would be relatively small, the effectiveness of the training would be maximum. The progress would be much better than could possibly be made in the same work with undergraduate classes containing many students not really qualified for or genuinely interested in such subjects.

I believe this combination of four years' liberal curriculum for all, and two-year graduate curriculum for those who are properly endowed for and desire it, would result in producing men better qualified to take their proper places in the world than are those who complete most of the present-day curriculum.

All engineering students should realize that it is impossible to escape passing through an apprenticeship period of some sort. A university curriculum cannot possibly replace the apprenticeship period except in the cases of the comparatively small number of persons who are preparing for research and highly technical progress. Therefore, it is extremely important that the curriculum be such as will aid in choosing the proper kind of apprenticeship to fit the individual's mental endowment and his aptitudes. There should be fewer misfits because the first four years' training would give them an excellent foundation, and they could choose the type of work most interesting to them. This would eliminate a very real difficulty now in common existence. For instance, a boy before graduating from high school has built radio sets, worked in a local power plant, or had some kind of electrical experience. Perhaps electricity appeals to him more strongly than any other subject. He wants a university education because he has been told that it will enable him to earn a good salary immediately after graduation, and will go far toward insuring success in later life. What then is more natural than for him to register in electrical engineering, because here is the opportunity, in his opinion, to secure the university education he wishes and at the same time specialize in his favorite subject. Naturally he has considerable pride in his choice and is reluctant to make any change even though the first year or two may prove that he does not possess the necessary types of ability to succeed in engineering. He may eventually graduate and begin work, still determined to be a successful electrical engineer. The result is in many cases an employe who has not the ability and characteristics necessary for his work. He must then work on as best he can and be a failure or only a mediocre success in electrical engineering, or find something to which he is better adapted. In so far as possible, a young man's interests and abilities should be determined before he graduates. If this can be fairly well accomplished and he can be sent out either with the broad four-year training, or better, with both it and the two-year graduate study, his chances of success should be greatly improved, and he should be a happier man in later life.

R. W. Sorensen: I would like to add to the list of books given at the end of Professor Ryan's paper one entitled, "Ions Electrons, and Ionization Radiations" by J. H. Crowther, published by Edward Arnold, London. That book is easy to read and it presents in a reliable manner much of the information about ions that engineers wish to know.

In the three papers bearing directly upon education, you will, of course, find differences of opinion, and so there should be. The biggest crime educators could be guilty of would be that of making a standard curriculum, which would be the same for all engineering colleges. In fact, we often remind ourselves at California Institute of Technology that we must not simply add to the group of good engineering courses in California just another course like the one at our State University or like Professor Ryan has developed at Leland Stanford. We at the Institute are spending annually about $700 per year per student enrolled, to carry on our work. That money has been given us by individuals for a specific purpose and should not be used to duplicate the work of other institutions.

Dr. Magnusson has sounded a keynote when he says every faculty man should do enough research work to show that he has the ability to inspire students in that direction. Some undergraduates are qualified to do research work along with their regular undergraduate work. Such men should be given an opportunity to do that work. Also, there should be graduate students, the more the better, doing research work, and the college should make such provisions for such a plan. In this way, every student has a chance to come in contact with research work, learn what it is, and methods of procedure. Every engineer will, to a large extent, have his success determined by the amount of research enthusiasm which he can develop, even though that enthusiasm is not applied to the type of problem ordinarily classified as a research problem.

As to the senior thesis for all, the discontinuance of that plan was due to several factors, one being lack of time on the part of the faculty to supervise many students and assign each student a problem of just the proper magnitude to fulfill the requirements for graduation. In place of the thesis, certain problems are assigned students, the problems selected being tempered by the circumstances under which the student is working. Such a problem does not have to be written in thesis form, thus allowing all the available time for work on the problem.

Why do we include four years of English in our curriculum? We have had complaints that the engineers are underpaid, and underpaid chiefly for one reason, that the engineer confines most of his contact with men to those who talk only engineering language, and there is no use to try to sell engineering information to other engineers unless you are a much better engineer than the other man, which doesn't happen very often. On the other hand, there are thousands of people in the world who want engineering information and who would take it if presented to them so they could understand it. You can't present engineering data to the artist in a way that he will understand it unless you know his language; you can't present it to the doctor, lawyer, or

merchant in a way that they can understand, unless you know something of their language.

Therefore, we have a department of English which runs through five years of our five-year course, and we must have a large department in order to keep the type of instructors we have, instructors whose business it is to inspire men and cause them to make of themselves all-round men. That is the reason we think it worth while to put in a five-year humanity course right along with a five-year technical course. Many of us would not do the things we do if some seemingly insignificant thing had not inspired us to go in an inviting direction. Without the instruction we would have failed in finding the doorway to new and interesting fields of endeavor.

In reply to the comments made by Messrs. Robinson, Clark, Henline and others, there are many details about which we could argue, but each exception only makes plainer the fact that all individuals should not be required to follow the same course of preparation for engineering work. Some men should prepare a thesis, some should not, some should have five years of education in the field of English literature, including some history and economics, others should find it more profitable to plan a different use of their time, but in nearly every case, I would conclude that in the essential things there are no differences of opinion—except as to relative values. This condition could not be otherwise because engineers differ as to details even in designing machines, when a much smaller number of variables are encountered than is the case when we attempt to form the character of the youth who will in the future be our engineers.

Reference to values in character building prompts me to direct attention to the value of the training obtained on the athletic field as evidenced by the success of many of our engineering students who participate in athletics. A survey of the condition governing athletics at many of our educational institutions indicates to me that the advantages of athletics are for the most part lost to engineers because training for athletics has become such a time-absorbing specialty as to make it almost impossible for an engineering student to be on his college team. Our educators in the technical field, and those who are our friends, should help correct this condition of affairs.

C. E. Magnusson: Mr. Robinson's remarks lead me to think that I failed to state clearly what I had in mind. I meant to say that education is essentially training to think; that engineering education is training to think along engineering lines; that the main purpose of engineering students during their four years in college should be to gain clear concepts of the basic physical laws underlying engineering and acquire the ability to apply these laws to the solution of quantitative practical problems. The rest of their college work is accessory to this backbone of engineering education and may vary widely for different individuals. It goes without saying that all live engineering colleges frequently revise their curriculums. At the University of Washington, the revision of curriculums in the college of engineering comes regularly on the calendar every four years, and many changes both in regard to required courses and their content have been made during the past twenty years. I am grateful to Mr. Clark for emphasizing the value to industrial establishments of research in our engineering colleges although this phase of the problem does not come under the title of my paper.

Improvement in Distribution Methods

BY S. B. HOOD[1]

Member, A. I. E. E.

Synopsis.—*The object of this paper is to point out how protective measures which have been applied to a low-voltage distribution network can be utilized to improve the operating characteristics of the entire distribution system, as well as materially lower its installation cost.*

Many of the developments herein described are novel departures from more generally recognized practises. They have all, however, withstood the test of time and usage.

The common neutral system of distribution described has steadily increased in its application since first developed by the author for use in Toronto, Canada, about 16 years ago. It is at present the standard system with a number of large utilities with an aggregate capacity of some 300,000 kw. The particular system described is that of the Northern States Power Company in the Minneapolis territory, representing about 60,000 kw., or about one-half the total output of this widespread organization.

The heavy duty a-c. underground network and the remote-control multiple street lighting systems described are both later developments that are more or less inter-related with this common neutral development.

PROTECTIVE GROUNDING

In order that the lives and property of the community may be protected against the hazard due to the low-voltage utilization circuits becoming crossed with those of dangerously high voltage, it is now compulsory to install protective grounds.

Such compulsory grounding requirements are embodied in both the National Electrical Code and the National Electrical Safety Code.

The desirability of such grounding is no longer a matter for question or argument, as it has, in innumerable cases, proven its protective value.

However, where such grounding is not carried out strictly in accordance with both the wording and the spirit of the rules in both codes, it is worse than useless in that it creates a false sense of security.

There is little question but that the responsibility of seeing that these grounding rules are enforced rests initially with the electric utility engineer. Unless he can create a more equitable division of the responsibility by transferring a part to the consumer through municipal regulation or company rules, his company must not only shoulder the responsibility but also the burden of total cost involved.

In a number of our large cities, such distribution is effected through the local inspection authorities, requiring that each and every service be properly grounded to the water-supply piping in the buildings served, this being done by the customer whom it protects and at his expense.

It is particularly unfortunate that a number of communities still refuse to make such regulations, even after the American Water Works Association has recommended that such grounding be permitted without fear of injury to the water system. In still other cases municipal authorities are not only trying to evade this responsibility but are attempting to exact a toll from the electric utility for use of the water system as a means of protection to the community. Where such unfortunate conditions exist pressure should be brought to bear to not only permit, but require, the use of the water system for protective grounding, as it imposes no burden or expense.

Where the low-voltage secondary network is adequately protected by grounding, there can be no hazard from high-voltage crosses, either accidental or intentional.

Any system of protective grounding to be effective must be capable of safely passing the heaviest current required to trip a feeder circuit breaker. Where the nominal feeder rating is 300 amperes per phase, it follows that about 500 amperes will be the tripping value.

It must be self evident to any engineer that to ground a section of secondary by means of one or two driven pipe grounds is hopelessly inadequate. Such grounds are, as a rule, incapable of blowing a branch circuit house fuse when a ground occurs on an outer wire on the customer's premises. This type of grounding was originally installed in Minneapolis and later reinforced by installing at least one service ground in each city block, using the water service for this purpose. This effectually eliminated the troubles due to former inability to blow clear accidental grounds on the outer wires of the secondary bus section. It was not, however, sufficient to protect against a heavy feeder cross between primary and secondary. In order to get the benefit of all existing grounds, by connecting them in multiple, the various secondary section neutrals were interconnected. This was a much smaller undertaking than might be supposed, in that service requirements made most of the secondary sections terminate within one or two spans of each other. In order to avoid placing an anchor guy at each of these ends, or a continuous head guy, it was general practise to carry the neutral conductor through these gaps and insert a strain insulator at the midway point. All that was necessary to interconnect these sections was to place jumpers across these numerous neutral strain insulators, as when this was done there was automatically established

1. Of the Northern States Power Company, Minneapolis, Minn.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., September 15-19, 1925.

a system neutral in the form of a vast grid or screen that blanketed the entire area served. With thousands of line and service grounds connected to this, the resistance to earth was so low that the heaviest current obtainable through any form of cross could be carried to ground with absolute safety and without raising the potential to earth of the secondary system by any appreciable amount. In later years the City Electrical Department has required that every new service must have its own protective ground, installed by and at the expense of the building owner to water piping where available. This has assured a perpetual improvement of grounding conditions with growth of the system, as over 5000 new services, with their grounds, are connected to the system annually.

In order to assure low resistance to ground, periodic tests are made between system neutral and water mains and where the results show in excess of one-tenth ohm additional service grounds are installed.

In districts outside the water main areas, service grounds are attached to driven well casings in preference to using driven pipe grounds or other forms of artificial grounds. These are only used as a last resort.

Wherever economically possible, the secondary mains are extended for new customers in preference to extending the primary and installing additional small transformers. With this plan it is assured that the system neutral will always cover a greater area than the primary system and that there will be no isolated secondary sections not amply protected by connection to the system neutral.

Since Minneapolis is very similar in layout to other large cities, it follows that the plan of protection outlined above may be applied to almost any typical community, and has been applied by the author to three of our major cities.

Primary Distribution Systems

With the rapid growth of the industry, developing load densities far in excess of those previously thought possible, it has become very evident that the once commonly used 2300-volt, three-phase, delta primary system was not only uneconomical, but also impracticable unless substations were spaced much too close to make their size or operating costs reasonably efficient. It was therefore logical to change to some form of system that transmitted at a higher voltage, but still permitted the use of the vast amount of transforming equipment already in service. The star connection of the older equipment was the natural solution of this problem, and today we find the 2300/4000-volt, star-connected, four-wire primary system almost universal in cities of any size. By stringing in a fourth wire for the neutral, and reconnecting the transformer primaries, the old 2300-volt, delta system can be changed to transmit three times the energy over the same distance with equal loss, or the same energy over three times the distance. In practise, it has enabled us to carry a considerable amount of extra energy over each outgoing feeder and at the same time space our substations much further apart, these also naturally being of larger size than would have been practicable with the older system.

However, in order to safely use the same transforming equipment as for the older system, it was essential that this neutral wire be definitely stabilized in its voltage to earth. This is commonly done by grounding the primary neutral at the substation, connecting it directly to a water main or other known effective ground. Each outgoing feeder is then provided with its own isolated neutral over which any phase unbalance on the feeder returns. Under normal operating conditions this has worked out very well and there is no residual current to cause induction on adjacent low voltage signal or communication systems.

However, under certain abnormal operating conditions this method of stabilizing the neutral has proven far from effective. We are all familiar with the complex conditions that arise on the old Edison three-wire, direct-current systems when, for any reason, a neutral is opened. In this later four-wire, three-phase primary system, we get very similar conditions except that the maximum rise in potential on any phase can not exceed 73 per cent above normal. When a single-phase short-circuit occurs, there must be a 2300-volt drop of potential on the phase wire and the neutral combined. Assuming that both are of same size, this means that the system neutral at the point of fault will be shifted out of its central position and the other two phases will have their potential raised about 36 per cent. If for any reason the neutral should open during the occurance of such a single-phase short circuit, then the neutral at point of fault will be shifted 73 per cent. Since either of these conditions impose an overstress to ground on all the transforming and protective equipment, as well as induce corresponding voltage-increases on the utilization equipment of the customer, such a system is very hazardous and uncertain in its operation. In the case of heavy phase grounds, excessive passage of current through the earth may result in interference to adjacent communication circuits through both earth potentials and high residuals in the line.

In order to guard against such conditions it has become general practise, where this type of system is used, to install single gap lightning arresters at various points along the primary neutral. These are supposed to break down at about 350 volts and thereby reestablish the relation of neutral to earth. In practise these do break down, but unfortunately or otherwise, very often stay broken down. In other words there are established numerous more or less unreliable points of multiple grounding on the primary neutral. Since there are no ready means of determining such relief gap failures, these grounds usually are permitted to remain on the system, just as are accidental grounds

permitted to remain on the neutral of any extensive Edison low-voltage, three-wire network.

It follows, therefore, that many so-called single point protective grounded primary systems are today operating successfully with innumerable unadmitted, neutral grounds. Occasionally induction in adjacent telephone circuits leads to temporarily clearing these grounds, but they soon reoccur unless constantly checked up.

In the development of the system as used in Minneapolis, it has always been openly admitted and claimed

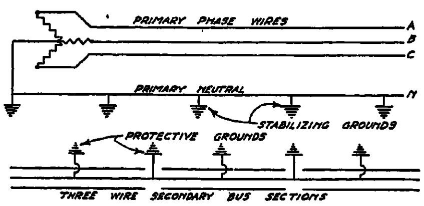

FIG. 1—DUPLICATION OF NEUTRALS

that a four-wire, star-connected primary system must have a large number of distributed multiple grounds on the neutral in order to make it practicable in operation.

By reference to Fig. 1 it will be noted that such a primary neutral is shown paralleling the system secondary neutral previously described. If this method is used, it gives two wires both held definitely at earth potential by numerous grounds. While the low-voltage

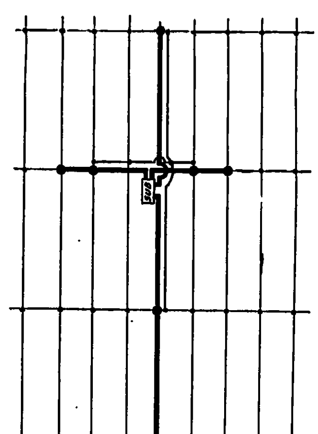

FIG. 2—NEUTRAL GRID

neutral can be adequately protected by means of service grounds, the primary neutral can not readily be so protected and, therefore, the necessary reliable grounds can only be obtained with difficulty, and ground wires must be carried down to the water mains buried under the streets. When, however, both neutrals are so protected, it follows that they are one and the same wire in so far as potential to earth is concerned, and, as such, may be combined physically. Where this is done we have what is now known as the "common neutral" system.

In Fig. 2 it will be noted how this common neutral forms many metallic return paths in addition to those through the earth. In order to avoid concentration of heavy currents on the system, due to abnormal operating conditions, neutral grid near the substation's heavy neutrals are carried out of the substation in several directions. These generally are extended for several blocks in each direction and tap the system neutral at each intersecting point. This arrangement is clearly shown by the heavy lines in Fig. 2, which represent the only actual primary neutral copper necessary where a common neutral system is used. All the other neutral is that required in the secondary system in order to obtain adequate protective grounding irrespective of the type of primary system used.

With this form of system, there are so many assured paths for both normal and abnormal neutral return currents that the entire primary neutral system is definitely held at earth potential. Normally the return current will take, by preference, the path closest to that of the primary phase wire, tests having shown that at least 65 per cent of the return will take this path irrespective of the number of other metallic paths established in addition to those through the earth. This is due to the close loop formed by the phase wire and its parallel neutral giving a far lower impedance than any of the wide open loops over other routes or through earth.

Since periodic tests show resistance values not to exceed one tenth of an ohm between system neutral and earth, it would appear somewhat inconsistent to find so large a percentage of the return current taking the metallic path closest to the phase wire unless one keeps in mind that this division is largely governed by impedance and not by resistance.

From the economic standpoint this system not only saves all the neutral copper required on the three-phase feeder of the ordinary four-wire system, except the small amount adjacent to the substations, but also eliminates one of the two wires on every single-phase branch taken off the three-phase line, and these form a considerable percentage of the total copper in any primary distribution system.

The transmission losses with this system are materially less than that of the more commonly used four-wire system in that the effective area of the neutral return is always greater. In general it would appear that for the portion distributed as single-phase load, including all branches and any unbalance on the three-phase routes, the loss will be from 25 to 40 per cent less.

Since the neutral is definitely stabilized at all points, it is no longer necessary to place protective equipment on both sides of the transformer primaries, the low side being tapped directly to the system neutral. This, of course, saves one-half the investment, troubles, etc., in such protective equipment.

In operation, the system has always proven far more reliable than either the usual form of four-wire system

or the older three-wire delta systems. This is partly due to the lower wire mileage involved, but more largely to the fact that only one primary phase-wire is required on all single-phase branches where most of the usual troubles occur. In such locations, the system neutral is spaced vertically and below the phase wire and can not be readily fouled with it. The general arrangement of the pole head on single-phase construction is shown

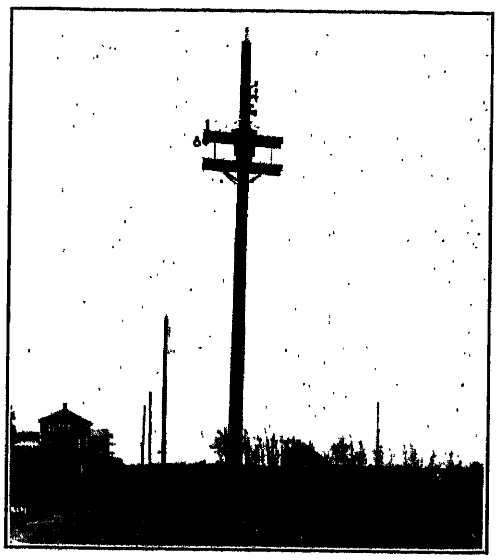

Fig. 3—Common Neutral Pole Head

in Fig. 3 which also shows the method of transformer mounting.

In order to permit of emergency operation of feeders, the general arrangement shown in Fig. 4 is adhered to as closely as typographical conditions will permit. Each feeder is provided with a single-pole, oil switch in each phase wire just before the loads are taken off. A series

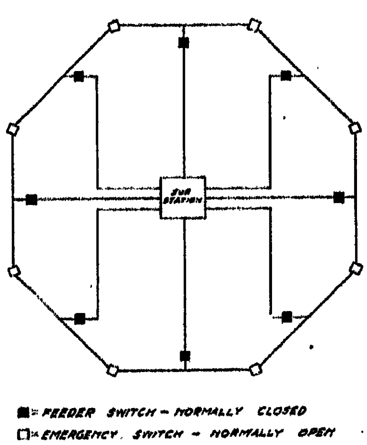

Fig. 4—Typical Feeder Layout

of emergency ties are installed between adjacent feeders, forming a ring in which each segment is sectionalized by groups of single-pole, oil switches, which are normally operated in the open position. This arrangement permits of taking the load from any one feeder and transferring it to at least two adjacent feeders.

Outside of this ring, the various phases are split up into small, single-phase areas, arranged as far as possible somewhat as shown in Fig. 5. The phase relations are distributed so that the minimum possible residual current is permitted along any one three-phase sub-feeder route. Since each feeder is of nominal 300-ampere rating per phase, it follows that each single-phase section is of about 240-kv-a. capacity. The section rings are adhered to wherever practicable in order to distribute the voltage drop as evenly as possible when covering a given mileage of street. A further advantage is that any break in a ring does not interrupt service, and when desired, such breaks can be cut out until repairs are permanently made under favorable weather conditions. The record of operation of automatic reclosing breakers has shown that it is very rare to have a feeder stay shorted after the third operation of the breaker, when it locks out. No fuses are used in any portion of the primary network as it has been found that these will blow under momentary overloads and will seldom blow under contact of a primary wire with

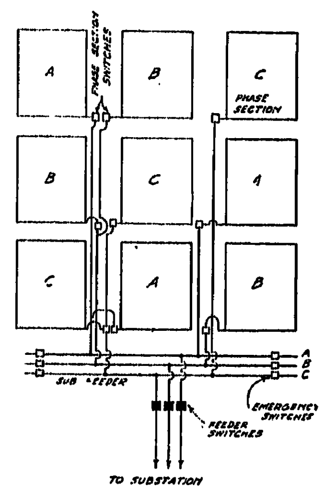

Fig. 5—Phase Area Distribution

the earth. Under such conditions they do not offer any material protection but do represent a hazard to continuity of service.

Lightning Protection

The ability of transformers connected to the common neutral system to resist damage from lightning is very marked.

On the Minneapolis system the total number of transformers burned out, from all causes, known and unknown, averaged eight-tenths of one per cent per annum, averaged over a period of three years.

Minnesota is noted for its severe and destructive lightning storms, and, therefore, this apparent immunity of the common neutral system can not be explained by lack of lightning hazard.

The use of the common system neutral, as a ground connection for lightning arresters, has not only fully

justified itself through favorable operating results, but was, in a large measure, adopted in self defense. Under the older and more generally used plan of having separate lightning arrester grounds, accidents due to arrester insulation breaking down and the baking out of the artificial ground occured far too often to justify the use of rules existing in defense of this method of lightning arrester ground connection.

For some unknown reason, the interconnection of secondaries is one of the factors in transformer immunity from lightning damage. It has been repeatedly noted that transformers feeding isolated secondary sections rather than part of the secondary network failed during lightning periods. Other transformers immediately adjacent to these isolated units showed 100 per cent immunity.

Inductive Coordination

The experience with the common neutral system in Minneapolis has very conclusively proven its desirability from the distribution standpoint, although under certain conditions which are now under investigation, it contributes to inductive disturbances occuring in adjacent communication circuits. It must not, therefore, be inferred that the common neutral system can be used without due consideration being given to proper coordination of the two types of circuits. Such coordination likewise implies a very close cooperation between the engineers of the two utilities.

In order to give full cognizance to the esthetic appearance of the streets of our communities it is advisable under certain conditions that the power and communication utilities use joint poles in overhead construction. It follows, therefore, that any practicable primary system of distribution must be such as will not appreciably impair the service of any well designed and maintained telephone system using the same poles as the power system.

It is not practicable to design or operate any power system that will be free from residual currents, neither is it practicable to design or operate a telephone system that will be so perfectly balanced that it will be void of susceptiveness to influences from the currents and voltages in the adjacent power system. The problem then narrows down to determining just how far either or both power and telephone systems can depart from the theoretical ideal and still give an entirely satisfactory service to all consumers served by both utilities.

To this end the engineers of both utilities have been working in very close harmony for some years. This cooperative work has culminated in the very elaborate and comprehensive tests that have been in progress for some months at the Minneapolis field laboratory and experimental line and which will not be completed until some time in the future.

Consequently, the results of these tests will probably not be available for general use for some considerable time; however, it is believed that within a short time the industry may look forward to an interim report covering the more important points of inductive influence and susceptiveness in the respective systems and the remedial measures that can be applied with a fair degree of assurance as to their effectiveness.

In actual practise it has been found that those remedial measures mentioned in the *Principles and Practises* of the Joint General Committee, such as reasonably close balancing of phases on the power system, the separation, where feasible, of the two classes of circuits, the grounding, where practicable, of aerial cable sheaths, and the use of high-impedance ringers, are valuable in reducing the respective influence and susceptiveness of the systems involved.

Other changes or additions tending to reduce interference are also possible at party line substations using grounded ringers.

Secondary Networks

Practically the entire Minneapolis system is operated

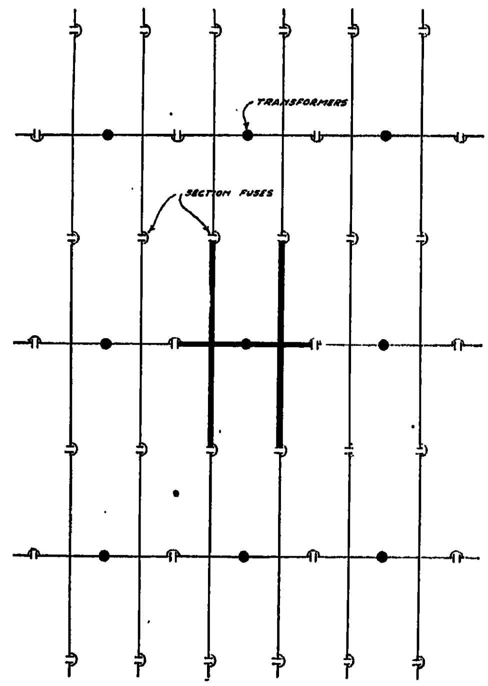

Fig. 6—Typical "H" Section Secondary Network

with the various secondary bus sections within any given phase area, interconnected. It has already been mentioned that the interconnection of the neutrals was easily accomplished, owing to the short gaps between sections. The outer wires of the three-wire secondary are extended in a similar manner and interconnected at the various midway points through copper-link limiting fuses proportioned so that they will blow if the current exceeds approximately 50 per cent of the capacity of the smallest adjacent transformer. Each transformer is also fused on its outer secondary leads by copper links which limit the current to about 200 per cent of transformer rating. The general arrangement of each secondary bus section is in the form of the letter *H* as

shown by heavy lines on Fig. 6. This also shows the adjacent secondary bus sections and the locations of the limiting section fuses between sections. It will be noted that any one transformer can drop out and the normal load on the section be easily carried by division between adjacent sections. In the event of a heavy

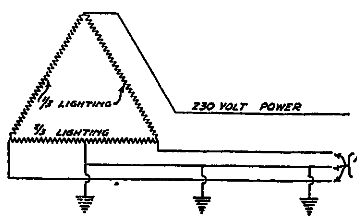

FIG. 7—FOUR-WIRE COMBINATION SECONDARY

secondary short circuit, both the transformer fuses and the section fuses will be blown and the defective section segregated from the network. This plan of interconnection not only assures reliability of service, and materially better regulation, but also takes advantage of about a ten per cent diversity factor between peaks on adjacent sections serving very similar loads. On

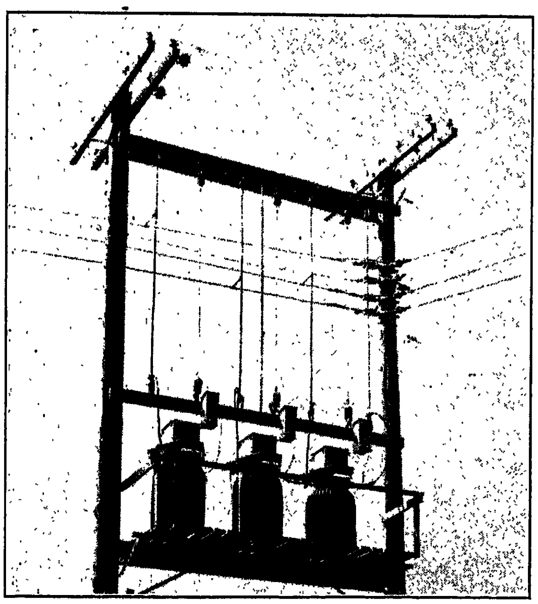

FIG. 8—COMBINATION TRANSFORMER INSTALLATION

ordinary residential service, transformers are regularly loaded to about 125 per cent full load rating on the winter system peak. This leaves sufficient reserve capacity to take care of emergency service to adjacent sections, as it has been found that transformers used for short-peak, winter service will safely carry up to 200 per cent rating. With this interconnection, it has been found that the primary neutral return current will split and a very considerable portion, at times as high as 60 per cent, will take the path through the secondary outside wires rather than through the common neutral. This materially increases the effective cross section of the common neutral and thus carries a greater percentage of the return current through the neutral in close parallel with the primary phase wire, thereby decreasing the extraneous return current for any given phase wire loading.

Where the power demand is a considerable portion of that for lighting, combination light and power transformer banks are used with the secondary delta tapped at the midpoint of one phase for the neutral. This connection is shown in Fig. 7 and a typical installation is shown in Fig. 8. With this connection one-third of the lighting load is carried by the two power transformers in vector series, the other two-thirds being carried by the lighting phase. It has been

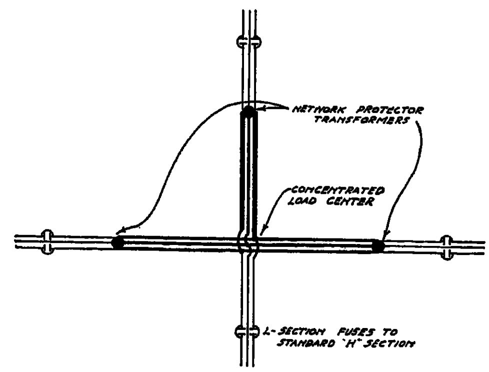

FIG. 9—THREE-UNIT NETWORK SECTION

found possible to carry both light and fluctuating power on these four-wire secondaries without material impairment of the regulation. Since the light and power peaks seldom directly superimpose, there is a very appreciable saving in investment where this connection is used.

For serving small commercial centers which develop close to intersecting car lines and which require a transformer capacity in excess of the average over the network, the secondary mains are of heavy copper, usually 4/0 gage, and the transformers are located at three or more points on the edge of the concentrated

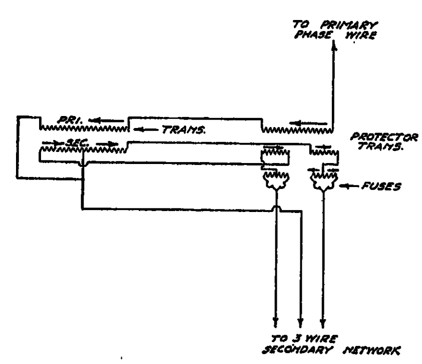

FIG. 10—NETWORK PROTECTOR

load district rather than near its center. This is necessary in order that there will be considerable impedance introduced between transformers in order to get proper division of load and selective sectionalization during times of trouble. The transformers used are provided with network protectors on the secondary

side and are thereby locked in on the system except in case of an actual failure within the transformer itself. The arrangement of these transformers is shown in Fig. 9 and the hook-up of the network protector feature in Fig. 10 the basic principle of which is simply neutralization of magnetic flux in the core of the auxiliary series transformer which is built into the standard transformer case. Any disturbance of this flux by reason of current reversal, due to internal faults, creates a potential in the tertiary windings across which the protective fuses are bridged. That this network system is not only economical but reliable is best shown by the fact that our transformer record for 1924 showed an average size transformer of 19 kv-a. and the burnouts were but seven-tenths of one per cent.

In the down-town, congested area of the city, there has recently been installed a heavy-duty, underground, secondary system, designed to take over all increased loads in this area, leaving the older d-c. system to continue in operation without growth until such time as it has depreciated to a point where its retirement can be justified. This sytem is served by transformers located in vaults built under the sidewalks. In general, each vault is provided with three 100-kv-a. units, although several have as high as 900-kv-a. capacity. The general arrangement is indicated in Fig. 11. The primary feeder serving this group of vaults is on the ring system, looping through each vault. On each side of the loop, automatic oil switches are installed together

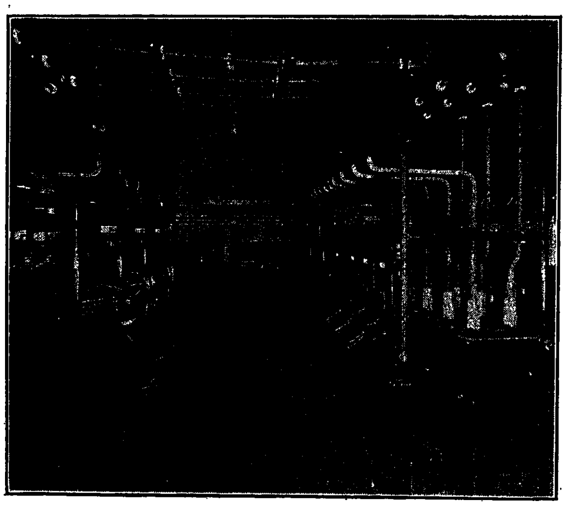

Fig. 11—Typical Transformer Vault

with relay trips. On the cable sections between vaults, the relays are differentially connected through pilot cables run in the same duct lines with the feeder. This locks the cable in except on faults in the cable itself. On the end sections of the loop the vault protection is by means of reverse power relays. At the major substation each end of the loop is provided with an overload-trip oil breaker and an automatic regulator. The control of the latter is cross connected to prevent hunting and hogging of the load.

In the two loops at present installed, as shown in Fig. 12, the substations are some distance outside the down-town area and normally serve a heavy demand in residential and apartment house service. By taking advantage of the peak diversity between this class of load and the down-town commercial and power loads, it has been possible to take on these down-town feeder loads without increasing the substation or transmission capacity. The use of 4000 volts has been justified in preference to direct use of the thirteen two-kv. trans-

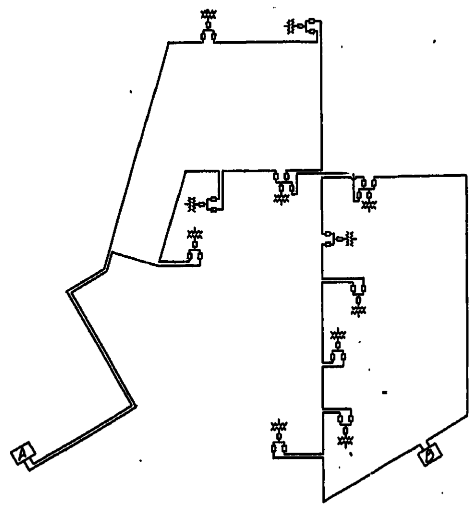

Fig. 12—A-C. Underground Primary System

mission voltage, by the fact that vault space is somewhat limited and it is difficult to get suitable spacing for higher voltage equipment. In addition, each loop can carry about 3000 kv-a. and distribute it over a substantial area. To make a higher voltage economical, a much greater area would have to be served from one feeder and it would be undesirable to take chances on an interruption so extensive.

The secondary of each transformer serves one phase of a four-wire, 115/200-volt, three-phase secondary. The ungrounded lead is protected by an air-break circuit breaker, controlled by a reverse power relay. The primary of each transformer is protected by either an overload oil breaker or a high-voltage fuse. In this network, both primary and secondary, the common neutral is used. Here in the underground district, the system neutral consists of not only copper conductors but all cable sheaths thoroughly bonded together. It also serves as the neutral for the Edison direct-current system, and has so served for many years.

In order to obtain standard 230-volt energy for power supply, rather than attempt to operate 220-volt equipment with 200 volts, small auto-transformers are installed in each vault. These are six to one ratio, dry type, and have ten per cent of the rating of the large transformers. This gives capacity for a 50 per cent division between lighting and power loads. From each vault, three-conductor, 500,000-cm. cables are carried out for secondary mains serving customers between

vaults. The use of separate cables for light and power has not proven uneconomical, as a single combined capacity cable could not be drawn into existing ducts.

In some instances where the power demand is small, dry-type auto-transformers similar to those in the vaults, but of only two-kv-a. rating, are installed on the building service panel and only the lighting mains carried in. Either two or three of these are used, depending upon the amount of power demand.

The operation of this system has been very successful and satisfactory. Heavy-duty, high-speed, passenger elevator service is carried on the same transformers as the lighting, with no appreciable interference with the lighting regulation. The auto-transformers appear to act as cushions for the heavy momentary power demands which have been found to cause considerable interference with lighting regulation where 200-volt service is supplied without these auto-transformers.

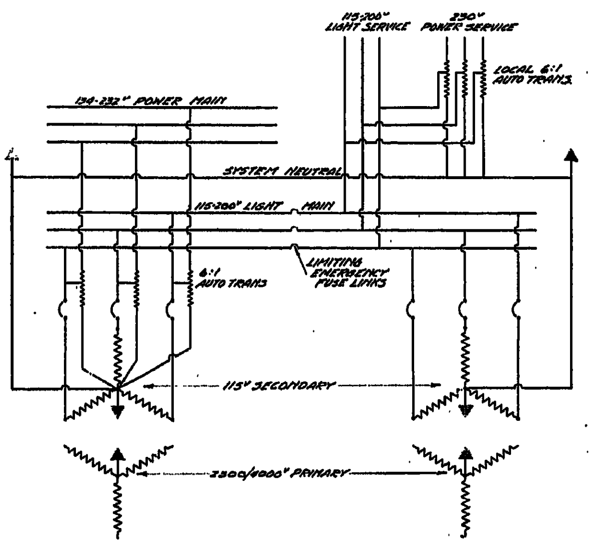

FIG. 13—TRANSFORMER AND SECONDARY CONNECTIONS

The general arrangement of the secondary system is shown in Fig. 13. As the system is extended, the lighting mains will be interconnected between vaults through limiting fuses in a manner similar to that which has worked out successfully on the overhead network. This will permit of emergency operation with any portion of a vault out of service.

STREET LIGHTING

Up to the end of 1923, street lighting in Minneapolis was by magnetite arc lamps suspended over street intersections, with the exception of gas lamps in some residential sections and five-light, ornamental cluster standards in the business districts.

For some years, we have been slowly developing a radically different system of street lighting distribution, using Type C incandescent lamps supplied with energy from existing distribution transformers and remotely-controlled by pilot wires. Late in 1923, when it was decided to abandon gas for street lighting, development work on this new lighting system was speeded up, and it was possible to start the first 500-high-c-p. units in service on January 1st, 1924. To these during 1924 were added additional lamps and this year some 500 of the old magnetite arcs are being retired, replaced with type C lamps. This will give about 2000 units in service.

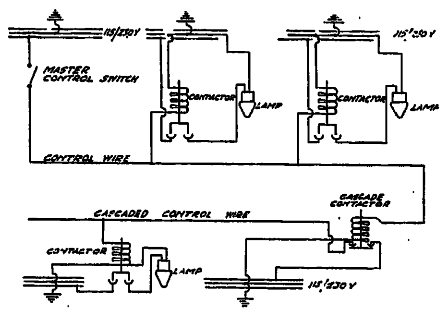

FIG. 14—REMOTE-CONTROL, MULTIPLE STREET LIGHTING SYSTEM

The general arrangement of this new system is shown in Fig. 14. The lamps are of two types,—those using the old form of mast arm suspension as shown in Fig. 15, with 1000-c-p. units at intersections and 400 c-p. for midblock lamps; the other is the new ornamental

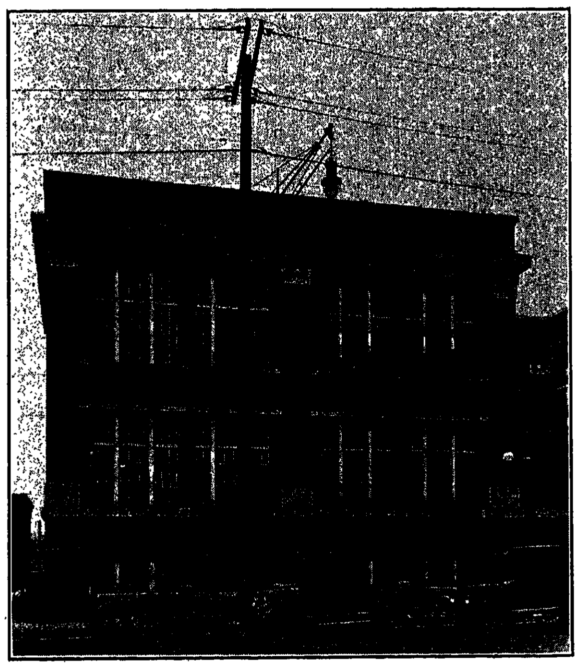

FIG. 15—MAST ARM INSTALLATION

system designed to supersede the ornamental clusters. The latter type, shown in Fig. 16, has been developed by the City of Minneapolis' engineering staff cooperating with the engineers of this Company. Electrically, the system is the same as that used for the general lighting.

The lamps are of the standard high amperage type as developed for series service. They are supplied from

small auto-transformers, using 115 volts on their primary, and installed in the lamp housing with suspended units, and pole bases for the ornamental standards. Each transformer is connected to the adjacent system neutral on one side, and on the other, to a section wire that in turn is connected to one of the secondary outside wires through a remote-control con-

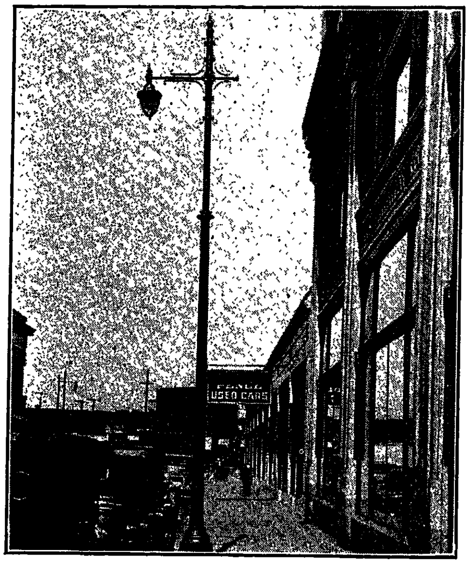

Fig. 16—Ornamental Standard

tactor. These contactors were specially designed for this system as they have to close by gravity and open electrically with a very small energizing current. They are of the mercury-cup type of the very simplest design and inherently free from trouble-making features. Their energizing solenoid coil consumes but 12 watts at 115 volts. The assembly of one of those is shown in Fig. 17.

For energizing these contactor windings, one side is connected to the system neutral and the other to a single-wire control circuit which is energized during non-burning daylight hours in order to hold the contactors in the off position. This assures that control system failures will not involve the lamps during burning hours. In the event of a control circuit or contactor failure, the lamps will burn during the daytime and trouble hunting becomes a daylight job at leisure rather than a rush night job in the worst of weather conditions. The control wires are carried out in each of four general directions from each substation. Here they are energized at 115 volts through a standard push button switch with indicating pilot lamps. In substations of the automatic type the energizing is done by electrically-wound clocks, fitted with astronomical dials which keep the schedule constant throughout the year.

When each control section has been extended to a distance and number of contactors where the voltage has dropped to about 80 per cent, a re-energizing contactor is inserted. These are similar to the other contactors except that they close the circuit when the solenoid is energized. These, in turn, take current from the nearest secondary mains and energize another section of control circuit. Since this can be repeated indefinitely, it follows that there is absolutely no limit to the area that can be covered with this type of multiple system using but 115 volts in any portion.

In operation, the system has proven so superior to any form of high-voltage series circuit that it is being rapidly adopted by other utilities and the various manufacturers are now prepared to furnish equipment for use with it at prices comparable with, or lower than, those for standard series operation. The average life of the lamps is running about 3000 hours with good sustained candle power up to the burnout point. With the low operating voltage and multiple operation throughout, failures are few and far between, the relative reliability of operation being about six to one in favor of the new system as compared to the older series circuits. The average lamp-hour outage is running about one-tenth of one per cent, which is remarkably reliable operation, meeting with the highest approval of the city authorities and the public in general.

In the selection of lamps for multiple street lighting,

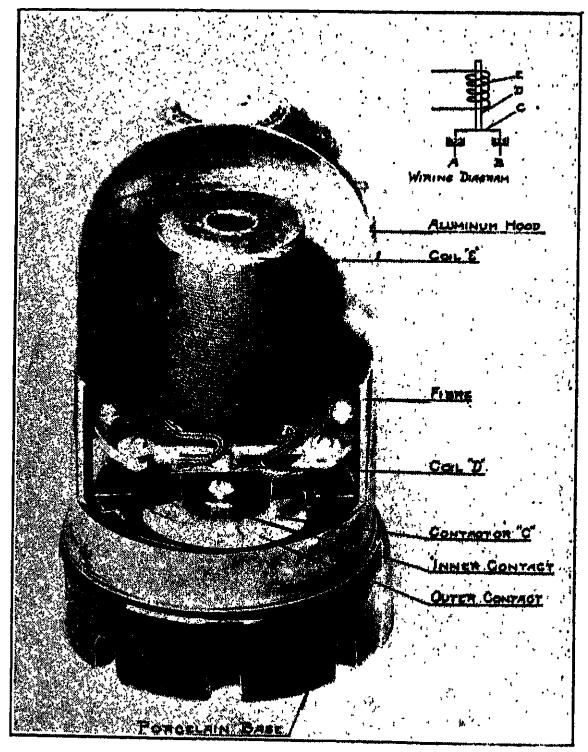

Fig. 17—Street Lighting Contactor

a much wider choice is available than with the series systems. Any of the usual series types of high amperage lamps can be coupled to the multiple circuit through suitable auto transformers, which are equivalent to the so-called compensator usual with series equipment.

While these series lamps are not specifically designed for constant potential service, they have given very

good satisfaction. The use of voltage taps on the auto-transformers permits of compensating for variable voltage loss in the 115-volt supply circuit. The long life of this type of lamp as compared to that of the standard multiple lamp is advantageous in that it lowers both lamp-renewal labor, costs, and lamp-hour outage. However, the lamp cost is approximately the same as that for the multiple lamp owing to the higher price put on the series type of lamp as compared to the standard multiple type.

Unfortunately, the lumens rating of multiple lamps and those of the series types do not match up, which makes it difficult to substitute one type for the other.

In the 10,000-lumen size, the series type can very well be replaced with the 500-watt multiple, giving 9400 lumens, thereby saving the cost of and losses in the auto-transformer. The possible disadvantage is that of more frequent renewals, about two and one-half times that for the series type lamp, and necessity of providing small auto-transformers for boosting excessive supply-circuit voltage drop on some long sections.

In the 4000- and 6000-lumen sizes, there is no multiple lamp substitute, as the 200-watt multiple gives but 3200 lumens and the 300-watt, 5100 lumens. However, where the series lamp lumen rating has not been established as a standard for any district, it would appear that the 300-watt multiple lamp could be used as a standard in place of a mixed standard of 4000 or 6000 lumens.

In the selection of lamps, it is desirable, where practicable, to use those of the multiple type as in that class the prospect for economic improvements is most to be expected.

If the series types are selected, and future improvements in lamp efficiencies are made, this type of lamp will change in its voltage rather than in lumens or amperage. Such a change would complicate the situation where auto-transformers of a definite, low-voltage rating are already in service.

Since the existing distribution transformers can usually carry the small addition of the street-lighting load, no transformer cost is involved and the existing high power factor is appreciably improved by this all-night steady loading. With the newer forms of series circuits the constant-current transformer cost is excessively high, its efficiency lower than for a standard transformer, and the power factor so low that they are very detrimental to the system.

Furthermore, the small auto-transformers used with high amperage lamps on series circuits will sometimes cause appreciable induction on adjacent communication and radio circuits when magnetically oversaturated when a lamp burns out. This effect is entirely eliminated with the multiple system. The comparative cost is roughly about 15 per cent in favor of the multiple system as compared to the latest types of series systems for either general or ornamental lighting. In addition, the over-all efficiency is about five per cent greater and the reliability and safety of operation much greater.

SUMMARY

The principal features which this paper describes are summarized in the following brief conclusions.

Protective Grounding. The maintenance of minimum impedance and ample current-carrying capacity from the secondary distribution system to earth, in conformity with the purposes of both the safety code and the fire code, is best effected by the adoption of a continuous network or wire grid for the secondary neutral covering the entire area served as one integral community with water-pipe grounds on every service connection and reinforced with bonds to water mains and driven-well casings where special circumstances justify it. Such use of the water pipes and mains for protective grounding purposes is not per se injurious to the water system, for extensive experience goes to prove that it is entirely harmless, and therefore municipal ordinances should require it as to the best interest of the public to be protected. Periodical surveys of the impedance to ground can be made very readily and constitute one of the advantages of this system of grounding.

Common Neutral System. In systems utilizing the 4000-volt, three-phase, four-wire type of primary distribution circuit, with single-phase lighting branches, there is substantial advantage and economy in combining the primary and secondary neutrals into one conductor, so as to serve both functions. It is a prime essential in the use of this system that the neutral be grounded in the general manner described in the previous paragraph, or its equivalent. With this system, the two outer secondary wires form an additional return path in parallel with the neutral, and the primary load current (in the single-phase instance) divides nearly in the ratio of copper cross-section. The return path via the neutral network is obviously of a complex nature in any given instance, but tests show that at least 65 per cent returns via the neutral on the same pole route with the primary. Each primary feeder district is served by a three-phase main which taps into a ring feeder through an oil switch, and the ring is sectionalized about midway between adjacent taps by means of oil switches which are normally open but can be closed in emergencies. The entire load area of each feeder district is divided into single-phase sub-districts, so associated and distributed among phases as to minimize the unbalanced load current in the neutral along any given three-phase route. The saving due to reduced investment is estimated at $8.00 per kv-a. of distribution transformer capacity and the energy copper loss is reduced variously from 25 to 40 per cent.

Inductive Coordination. The use of a common neutral system may be detrimental to the service rendered by adjacent telephone circuits unless proper coordination

is applied through close cooperation of the engineering personnel of the two utilities involved.

Pending completion of the joint tests now in progress, and a review of the results, definite recommendations can not be given other than for the use of such remedial measures as are now already known and recommended in the "Principles and Practices." The results of these tests, so far as some of the more important features of the problem of inductive coordination are concerned, will be available, it is expected, at a comparatively early date.

Secondary Networks. The secondary mains in any given phase area are interconnected by means of copper link fuses in the two outer conductors, which are proportioned so as to operate on approximately 50 per cent of the rated continuous capacity of the smallest adjacent transformer. The two outer secondary leads of each transformer are fused at about 200 per cent of rating. On ordinary residential service, the transformers are regularly loaded to about 125 per cent of rating on the winter system peak, but for short winter peaks will safely carry 200 per cent of rating. The typical layout of a secondary bus section resembles the letter *H*, as shown in Fig. 6. For mixed power and lighting loads a three-phase bank is used, as shown in Fig. 7. Local outlying commercial centers are served by means of the type of secondary layout and protection scheme which appears in Figs. 9 and 10.

Downtown A-C. Distribution. In the downtown area of Minneapolis an a-c. distribution system has been installed for ultimate relief of the three-wire Edison d-c. system. The 4000-volt primary feeders are arranged on the loop or ring system indicated in Fig. 12. Transformer installations are placed in vaults built under the sidewalks. At each substation supplying a loop there is overload protection on the outgoing feeder and also an automatic voltage regulator. Between vaults, the cable sections are provided with differential protection which functions only on a fault in the cable itself. The primary bus in each vault is equipped with reverse power protection and the primary of each transformer is provided with overload protection. The type of secondary layout is indicated in Fig. 13 and the common neutral system is used here also. Separate secondary mains are used for lighting and power. The three-phase lighting mains operate at 115/200 volts. The voltage on the power mains is raised to 133/230 volts by means of six to one-ratio auto-transformers and these mains are equipped, in each vault, with reverse power protection. In special instances, where the power demand is not large, these auto-transformers are installed at the customer's service connection, and supplied direct from the lighting main. As this downtown system is extended in future, the lighting mains will be interconnected between vaults, through limiting fuses, in the same manner that has proven successful in overhead distribution.

Street Lighting. The constant-current series type of distribution circuit is being replaced with multiple distribution under remote control by means of a pilot wire and individual contactors at each lamp. The type of circuit layout is shown in Fig. 14. This system is made possible by the fact that 115/230-volt secondary mains cover the lighted area of the city very completely. This additional load on the secondary system proves very desirable from an economic standpoint. Experience also proves that the multiple system is more economical, efficient, and reliable than the series system which it is replacing.

Discussion

R. E. Cunningham: I have particularly noted the first paragraphs of Mr. Hood's paper regarding the necessity of thoroughly grounding secondaries and I want Mr. Hood to know that I concur with him in his statements.

I believe that too many of us have been content to drive a pipe or two connected to each secondary system and call it good enough. We all know what may happen to such grounds, particularly in dry districts. I think we should arrange through local ordinances to have a ground connection made at each customer's service which would be installed at the same time the house is wired by the contractor. This should be a water-pipe ground.

Now, as to using a common neutral, Mr. Hood, no doubt, has a condition where, as he has stated, his plan has worked satisfactorily. Whether it would work under conditions obtaining in Southern California is a little doubtful. We have a long, dry season and a good ground is hard to get; in some cases it is impossible. There are very few districts where we have continuous water-piping systems and in some cases cement is used in making the joints in the pipes.

Thus far on our 4-kv., four-wire systems we have adopted the practise of grounding the primary neutral at frequent intervals, generally by the use of a driven pipe. We have not tried the plan of using the same wire for a secondary neutral.

I might say that in most cases we do not have secondary systems continuing throughout the primary circuits, so that possibly there is not the same opportunity for economy as exists with Mr. Hood. With the system as I stated, using the driven-pipe grounds connected to our neutrals, we have had a number of cases during the dry season when the phase wire has fallen and lain on the ground without kicking out the circuit breaker at the station. We are particularly concerned as to how to take care of such a hazard.

We have recently built a new substation in a district where the system was being changed over to 4-kv. four-wire and are trying out the scheme as shown in Fig. 1 herewith. Here the neutral wire is isolated from the ground except at the station and there the connection is through a current transformer, the secondary of which is connected to an ammeter and relay. This relay in turn can actuate an alarm bell. Any current in the neutral due to unbalanced load will not indicate on the ammeter or cause the relay to function, but any current returning to the station from a phase wire which might fall on the ground must flow through this current transformer.

The current transformer is provided with taps and the relay so adjusted that it will operate when one ampere flows through the ground connection. Tests have been made which show that about that amount of current would flow when a coil of bare wire connected to a phase wire was thrown into a patch of green grass at a distance of about one mile from the station. Normally adjustments are for a much higher current so as to protect against a

full ground and then once each hour the operator makes a test using the one-ampere adjustment.

We hope with this device to discover cases of phase wire on the ground under such conditions as not to cause sufficient return current to trip the circuit switch.

I would like Mr. Hood's advice on our situation and also wish to inquire whether with a phase wire down he usually gets enough current through the ground on his 4-kv. circuits to release the circuit switch.

E. R. Stauffacher: The ground relay mentioned by Mr. Cunningham will ring an alarm only when a current of one ampere or more goes back to the station from the line lying on the ground, whereas, our test indicates that only 0.3 or 0.4 ampere actually flows back to the station when a line is down on a 4000-volt distribution circuit about one mile from the substation. This, or course, applies to the dry soil condition. The equipment would indicate properly and give an alarm if the wire happened to be lying in green grass or in wet soil or against a green tree. However, there is every reason to expect that it will be rather difficult to develop equipment which will indicate when a line is lying down in dry soil or on a concrete or asphalt pavement. This leads me to believe that it would probably be better practise to install numerous grounds along the distribution line in addition to the ground at the substation, and to make every effort to see that the circuit breaker tripped out in case a wire dropped to the ground, rather than attempt to develop some type of ground detector which would indicate this hazardous condition.

C. A. Heinze: In Los Angeles, we have made use of grounds to water pipes for some years past. Our method is to select at least three services on each secondary and ground the neutral of each service to the local water pipe on consumers' premises.

It seems that ten or fifteen years ago the water department of our city experienced considerable trouble and difficulties with electrolysis. I imagine that a number of members know the full meaning of that word when applied to water systems, and the difficulties with electric railroads. To protect itself, the water department in Los Angeles constructed mains with cemented joints, thus preventing the possibility of getting a good ground by attaching directly to the main itself. However, on a three-wire service if we can obtain permission from the consumer, we bring down the neutral, connecting it directly to the water service. For mechanical reasons sometimes we use a piece of conduit, bonding it at each end.

I am a bit surprised to learn that Mr. Hood would like to have us go back to the multiple street-lighting system. It seems to me off-hand that we would be taking a step backward. I remember quite well that years ago we all, more or less, had multiple street-lighting systems, and we gave them up for the supposedly more efficient series system. Now, I find there is a tendency to go back to the multiple system again. I don't know whether the telephone engineers have had anything to do with this or not. At the same time I can't believe that it is a step in the right direction. Mr. Hood proposes and does install a contactor for connecting each lamp to the secondary bus nearest to the location of the lamp. From his paper I gleaned that it will require twelve watts of energy to keep this contactor energized during the daylight hours, and of course, during the hours when the lamp burns, the contactor is out of circuit or de-energized.

In Los Angeles, excluding the ornamental post lamps, we have 10,000 street lights of the suspension type. Now, if the contactor were to be provided for each one of these lamps in order to operate it on a multiple system as recommended by Mr. Hood, our loss in energy, valued at one cent per kilowatt hour would amount in a year to practically $7000. I don't know what Mr. Hood's company receives for energy for street-lighting purposes in his city, but surely none of us in the West are making sufficient money on street lighting to stand a yearly loss of any such amount, in our case amounting to $7000.

I can't see what the future holds for us if we go to a multiple system. I would like Mr. Hood to explain the reason for going to the multiple system. I have always been given to understand that the multiple lamp, toward the end of its life, greatly decreases in candle-power, while the series type tends to burn at full candle-power until it burns out. I feel that this will result in a large number of lamps being continued in service at reduced candle-power and not being replaced until they actually burn out, resulting in decreased illumination on the streets. I think we, as utilities, should strive to give the public all they are paying for and the best street lighting possible.

M. T. Crawford: I notice that the neutral return path described by Mr. Hood is apparently largely in the secondary neutral grid. I would like to ask if single-pole switches are used or three-pole switches on the outgoing feeders at the substation. It would appear that if single-pole switches were used and single-phase short circuits occurred, opening one or two switches, the neutral would be called on to carry the full-load current of the phase which remained in service, greatly increasing the duty of the neutral path, and I should think increasing the troubles that might come from using only a relatively light-capacity neutral grid.

Rather extensive use is made of fuses in the secondary main for sectionalizing in case of trouble. I would like to ask Mr. Hood what method he has for finding out when these secondary sectionalizing fuses blow. If secondary sectionalizing fuses should blow and no knowledge was had of the fact, they might stay open for some time and interfere with the proper interchange of load current.

Mr. Hood refers to the fact that the primary-neutral return current sometimes will split and take the paths of the secondary outside wires, rather than all go through the common neutral. I would like to ask if he has made any test which would determine whether or not this disturbs the voltage regulation on the secondary at such points. It would seem that it might have considerable effect on the voltage drop on the secondary bus and would affect the consumer's service.

In regard to the underground system, I would like to ask if Mr. Hood has experienced any operating difficulty in connection with the relay contacts. On the underground distribution system in Seattle where a large number of power-directional relays are installed, we have found it necessary to periodically inspect and clean the relay contacts. The gases and other substances in the subways appear in some way to cover these contacts so that they do not always function.

D. K. Blake: I find a large number of people who are strongly in favor of the common neutral and just as many who are strongly opposed to it, but the chief cause for opposition seems to be the telephone interference.

As to the multiple lighting circuit, there are a large number of eastern companies who are going into that, studying it, and applying it. I was very much surprised to find in Denver that the business section was supplied with multiple circuits with cascade pilot-wire control.

Mr. Hood referred to his polyphase secondary network for the business section which is a seven-wire system. There is a somewhat different type of system used by a large southern city of about 200,000 population. They have the same idea, that is, they do not want to supply an off-standard voltage to their customers' devices so they take the secondary winding of the transformer and extend it to 133 volts, which gives 230-star volts for the motors, and of course, a seven-wire system.

As to the matter of neutrals carrying load current, you might be interested in knowing that there is one large company which makes the practise of connecting distribution transformers from one wire to the grounded cable sheath and in that way

they have the cable sheath carrying a number of amperes of load current.

D. I. Cone: As already stated, the subject of distribution systems is of great interest to telephone engineers; one item in particular in Mr. Hood's paper presented today is of importance from that point of view; that is the question of the use of a common neutral for the primary and secondary ground connections and, also, the question of the multiple grounding of primary neutrals. I shall not undertake a discussion of that problem because we have attempted to cover the subject pretty thoroughly in the paper by Dr. Trueblood and myself.[1]

Mr. Heinze referred to the interest of the telephone engineers in the street-lighting problem. There is a paper by Mr. McCurdy which discusses series street-lighting systems from this point of view[2]. As to the multiple street-lighting arrangement, I think, without having had experience with it, that the multiple scheme would make coordination with the telephone plant much easier.

G. H. Smith: I would like to say a word in discussion of Mr. Hood's multiple street-lighting system. We have been living with an overhead series system in Seattle for twenty years and for the last five or six years we have been trying to find some way to dispose of it. The underground lighting system in Seattle is multiple, and the lamps are low-voltage, fed by transformers in the pole bases. We are averaging about 4000 hours' life on these lamps. It is hard for us to believe that we should use a 120-volt multiple lamp for that service although I believe that is the lamp manufacturer's recommendation. We hope before long to install an overhead multiple lighting system very similar to the one described by Mr. Hood. We have been working on it for years, and believe that it will justify itself from the standpoint of safety alone. Also, our figures seem to show that it will be fully as cheap and more reliable.

S. B. Hood: Mr. Cunningham has brought up the point as to whether the common-neutral system was suitable for California. I think probably the best way to find out would be to try it. The main thing in the common-neutral system is to have sufficient neutral copper so that the earth does not form a part of the return, not an essential part. Therefore, if the air conditions are very dry, all that is necessary is to equalize the potential between the neutral system and the earth, so I rather think that the point of safety would be just about on a par with the dryness of the earth. If the earth is absolutely dry, it is a perfect insulator, so if you maintain your neutral at earth potential at the interconnection, you never would get any appreciable difference between that neutral system and the earth, even though the earth conditions give very high resistance.

On the question of the opening of the circuit breakers in case of a fault to ground, I suppose what Mr. Cunningham meant by ground was the conductor lying on the ground. My experience has been that it doesn't make any difference what kind of a system you use, isolated-neutral or common-neutral, you cannot depend on opening a circuit breaker on contact to ground. The artificial ground connection such as a driven pipe will not have less than 100 ohms resistance. Now, you can readily see that 8 or 10 ft. of 3¼-in. pipe will not give a good ground. The contact resistance of a wire on the ground may be up in the thousands of ohms. So I don't think it makes any difference; you can't depend on opening the breakers through accidental contact with the earth.

Mr. Heinze brought up the question of the individual house grounds, and the difficulty of getting continuous grounds through the water main. I think that is probably common all over the country, possibly not to as great an extent as in Los Angeles, but you get the benefit of the buried pipe which forms a service pipe from the main, including the section of main in which that service pipe is tapped. So in the aggregate you have a fairly good surface of water pipe in contact with the earth, certainly much better than you could ever expect by an artificial ground. When you interconnect all of those grounds by a system neutral, you can count on pretty good protection.

I am sorry I can't agree with Mr. Heinze about the multiple system being a backward step. We think it is the greatest step forward we have ever made. I have felt for a great many years that the practise of running series circuits, which may have potentials up to 6000 volts, through alleys, and out to every street corner, networking the whole area much more highly than the primary circuits can, comes pretty near to being a crime, and there are probably more accidents to the public and to the utility's operating staff through those high-voltage series circuits than any of the other circuits you operate. The only trouble in the past has been to get the same efficiency in transmission with the multiple system. That can be solved by utilizing the distribution transformers, and the relay control system. Our experience with the maintenance of candle-power in the lamps has been remarkably good. I have always criticized the series system on a basis that the lamps, unless you break them up, will get so dim that you can't see whether they are burning or not.

Regarding the contactor losses in the multiple system, I think you ought to get the right point of view. You must consider that the series constant-current transformer at best will have only an efficiency of about 85 per cent, whereas the contractor uses 12 watts only for initial action, and as soon as the core rises it chokes the consumption down to 8 or 9 watts. That represents less than 2 per cent on a 500-watt lamp, and in a great many cases a group of five or six lamps may be found on one contactor. You can readily see the contactor losses are almost negligible compared to the losses in the series type of transformer.

The principal advantage we found in the multiple lighting system has been the better service during storm conditions. It frequently happens during a bad storm that lamp outages on the series circuits will run 17 to 20 times as high as on the multiple. As soon as the storm starts you will see the multiple lamps winking like stars all over the city. It can readily be seen with the series system that each accident or effect of the storm which has lit the multiple lamps would have put out of business the series type of circuit.

The question of maintained candle-power is one which I think we shall have to leave to the engineers of the lamp association. We picked the series type of lamp and adopted the multiple system, believing that the series lamp was the best of the two lamps. Now, they tell us that the series lamp was a poor lamp at its best, and we should use the multiple lamp, so I don't know which is right. Experience will have to show. I think, however, that one feature in favor of the series type of lamp, particularly in our large cities, is its longer life. They claim series lamps used on multiple system will give 2160 hours' life. We are getting 3000 hours on ours and better, and very well maintained candle-power. They also claim the multiple type of lamp is good for 1300 hours. My experience with the large systems is that if you get 1000 hours life out of it you are lucky.

Now, where you have cars parked along the streets all day and most of the night, when are you going to get a maintenance car up to the ornamental lamps? The men must go around before sunrise, and even then you will find many cars.

Mr. Crawford asked whether we use single-pole or three-pole switches on our feeders at the substations. Originally all our lighting feeders, before we converted to the common neutral, were the two-pole. Thus the only change we made was to change the original double-pole switches; the two poles were put in

1. Power Distribution and Telephone Circuits, by H. M. Trueblood and D. I. Cone, A. I. E. E. JOURNAL, December, 1925, page 1353.

2. Induction from Street-Lighting Circuits, by R. G. McCurdy, A. I. E. E. JOURNAL, October, 1925, page 1088.

series, giving twice the breaking capacity. Those circuits, however, were almost entirely lighting circuits and we found that the action was substantially that of a one-wire single-phase circuit. They didn't act as three-phase circuits at all. However, all our three-phase power circuits had three-pole switches, and as we cut to combination feeders, we found the single-pole switch had no advantage, due to the fact that among the other peculiar things we do, we always ground the neutrals of our three-phase power transformers. When you get a single-phase short circuit, the closed secondary delta transfers the short circuit to a very considerable extent to the other two phases, so that all three switches would go out in the same way as though they were on a three-pole switch. For that reason, as we rebuilt our substations, we conserved substation space by putting in entirely three-pole switches. In the modern substation with automatic closing equipment, it is the fact that almost always a circuit will not lock-out but will burn the fault off.

The matter of locating blown section fuses is largely checked up by periodic inspections made just before the fall peaks. During the summer season, most of the load in the interconnected districts being residential load, it doesn't make much difference whether those fuses are in or out except in some places where the range load is heavy. We make careful inspection just prior to the fall peak, and from then until we pass the overlapping period, the spring of the year, we depend on the customer to let us know when those section fuses are out. Generally he doesn't waste much time in doing so. In other words, our transformers will carry the load with those fuses out as well as with them in, but the regulation would be very much poorer; therefore, we almost invariably get a complaint from a customer when a section fuse is out.

We have never had any trouble with the effect on secondary regulation caused by flow of current in the neutral. There is under certain rather abnormal conditions a tendency to unbalance voltage, but you must have a very abnormal condition to bring out that effect.

Regarding Mr. Crawford's question as to relays in the underground a. c. system, our condition is possibly just a little different from what he may have in mind in that our transformer vaults are to all intents and purposes substations. We don't have the dampness and the gases found in an ordinary manhole vault. We are particularly fortunate in Minneapolis because we can put vaults under the sidewalk, and they are just as dry as the basement of a building; in fact, they are virtually the front of the basement. We use the same type of relays and equipment as used in the ordinary substation, and they are inspected periodically, in most cases once a week.

In Mr. Blake's remarks, he referred to a system in the South which used 133-volt transformers. That is the type of transformer with the 133-volt secondary tapped at the 115-volt point. We had considered that, but the objection we saw was that it made a semi-special transformer which is objectionable from the standpoint of simplicity in warehouse stock where it is necessary to stock one type of transformer for overhead distribution and another for underground. If the underground required a special type of transformer, probably that tap would be all right, but in our case we have adhered to standard equipment throughout.

Power Distribution and Telephone Circuits

Inductive and Physical Relations

Member, A. I. E. E.

Synopsis.—*Consideration of the relations between power distribution and telephone systems is naturally involved in any comprehensive review of the problems of the rapidly expanding power-distribution networks in this country.*

Avoidance of contact and provision of suitable working conditions for employees in situations of close proximity are dealt with in the National Electrical Safety Code and in State Regulations which provide arrangements for safety where complete separation is not feasible.

Induction from distribution circuits has heretofore had less general attention than induction from power-transmission lines. Recently the Joint General Committee of the National Electric Light Association and the Bell Telephone System has undertaken comprehensive investigations of these problems. Of particular interest is the study of induction under joint use conditions now progressing actively at Minneapolis. Pending completion of this and other studies, a preliminary and qualitative discussion is here given.

Situations of exposure fall into three groups determined by the character of the area served: (1) "downtown" districts; (2) residential urban districts; (3) rural districts. The major problems arise in the second group. A wide variety of arrangements characterize both systems, and require consideration.

Among technical features, coefficients of induction for close exposures, shielding action of metallic cable sheaths for both power and telephone circuits, and "ground potential" effects are distinctive problems. Where both classes of circuits are in cable with suitable precautions as to grounding, interference is rarely to be anticipated.

Low-frequency induction due to transient power-system disturbances is rare at the lower voltages but may assume great importance with higher voltage circuits, unless the amount of exposure or fault currents are suitably limited. Various methods for reduction of disturbing effects are discussed.

Noise induction from power-distribution circuits is chiefly from residuals which occur on single-phase branches of polyphase circuits, or where triple harmonics or load-current unbalances are introduced by grounding neutrals, or where admittances to ground of phase wires are unequal. Residual currents are largest in systems having multiple-grounded neutrals, both load-currents and triple harmonics occurring. Approximate resonance at triple harmonic frequencies between the inductance of station apparatus and power cable capacitance has characterized several situations. Various single, two- and three-phase arrangements are compared from the induction standpoint.

The closely related matter of unbalances in the telephone plant is briefly discussed. This is one of the subjects on the joint research program.

With the great variety of specific situations encountered and the growth to be expected, joint study by power and telephone engineers of existing cases and future plans furnishes the only practicable solution.

INTRODUCTORY

In any comprehensive consideration of the varied problems of our rapidly expanding systems of power distribution, there is naturally involved a discussion of the problems of relationship between these systems and the communication systems, which to a very large extent serve the same customers. Such a discussion is undertaken in this paper in the hope that a better understanding of the physical and inductive relations of different distribution circuits and neighboring telephone circuits will promote the coordination of the two classes of circuits without imposing undue restrictions on the development of either.

To appreciate the magnitude of the problem, it will suffice to recall that the number of power consumers in the United States has now passed 16 million. There is no present indication of abatement in the rate of growth, now about 15 per cent annually in number of consumers and in total load supplied. The number of telephones is likewise approximately 16 million. The growth of this companion electrical industry is today less striking (about six per cent per year) only because its period of rapid expansion began some years earlier. To a very large degree the customers of the two services are the same people; hence it is apparent that the combined growths present a problem of continually increasing proportions.

In and near the great centers of population, this growth of the two kinds of service to the public has led to the development of two highly specialized electrical systems of which large parts are necessarily in close proximity to each other. The most obvious consideration in this relationship of power and communication circuits is to avoid contacts between conductors at crossings and conflicts, and in the joint use of poles. A closely related matter in such situations is that of providing climbing and working spaces so that men can work on conductors and equipment of either class in a safe and convenient manner. These factors, and the necessity of limiting the numbers of poles on streets, led early to the development of specifications to govern clearances and strength of construction, and to extensive arrangements for the joint use of poles.

Contacts between power and communication circuits must be carefully guarded against, since they not only cause interruption of service on either or both systems, but may result in injuries to persons or damage to property such as (1) electric shock to employees or subscribers; (2) acoustic shock or noise; (3) breakdown of lines and equipment, with attendant fire hazard and destruction of plant. The intimate handling of telephone instruments in daily life requires the greatest

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

precautions to prevent their energization at dangerous potentials.

Standards for minimum clearances, for strength of construction, for insulation and other protective measures in both classes of circuits have been gradually established through long experience, the various features being continually under review as the arts progress. These standards include provisions against breakage or excessive sag of the upper conductors or breakage of supports at wire crossings, and against accidental contacts between wires of a given circuit, or failure of insulation.

In working out the relations between overhead lines of different utilities where the higher voltages are involved, the natural first line of action is to endeavor so to locate the lines as to eliminate the possibility of contact. This is in recognition of the increased hazard to persons and the impracticability either of building the communication plant to withstand damage by breakdown or of providing protective devices to limit effectively the amount of plant exposed to such breakdown. The problem of avoiding hazardous conditions is one not only of current- and voltage-limiting devices at circuit terminals, but of the insulation, clearances and operating practises over the entire exposed plant. Where it is found impracticable to avoid proximity, particular attention is required to the provision of adequate strength and arrangements of construction.

Preferences and minimum strength and clearance requirements for crossings, conflicts and joint use of poles by power and communication circuits have been embodied in the National Electrical Safety Code[1] and in the regulations of many of the states. The Joint General Committee of the National Electric Light Association and the Bell Telephone System[2,3], proceeding with these as a basis for further study, has subcommittees at work on both the contractual and technical phases of the problem, in recognition of the changing conditions of distribution practises.

Until recently, recognition of the importance of the problem of the inductive relations between power distribution and telephone networks has not been so general as that accorded a good while ago with respect to the association of long power and telephone lines. It is true that specific situations arose, some of them of rather large importance, sufficiently critical to require the development of measures of relief. However, the problems involved in the close inductive relations of power-distribution circuits and the telephone plant were not attacked on a large scale until they were taken up by the Joint General Committee of the National Electric Light Association and the Bell Telephone System, as part of the wider question of methods of coordinating the facilities generally of the two services for the avoidance of interference. This Committee has already published[3] certain recommended practises, mainly qualitative, which are applicable to the situations with which this paper is concerned. A Subcommittee on Development and Research is now engaged in comprehensive investigations of the various technical questions connected with this matter, and one of the "projects" under which the work of this Subcommittee is organized, is devoted to a single important aspect of the problem,—the question of induction under joint-use conditions.

1. Reference numbers apply to Bibliography appended hereto.

At the present time, the Committee in charge of this project is working in cooperation with the Northern States Power Company and the Northwestern Bell Telephone Company, using a most complete temporary field laboratory and experimental line in the outskirts of Minneapolis. While this work is progressing favorably, it involves many problems of a fundamental nature, and therefore does not permit of giving quantitative results until further advanced towards completion, which will require a considerable period of time. It is believed, however, that within the next six months an interim report can be issued dealing with those factors and remedial measures which are of prime importance to a solution of the problem.

This paper is thus of a preliminary and primarily qualitative character. It undertakes to present a view of the problems arising from inductive effects which are peculiar to the close association of extensive networks of the two utilities in and near centers of population, and discusses certain phases in some detail, with illustrative references to operating experience.

It is not proposed to deal with the subject of electrolytic corrosion of underground structures, a problem which involves not only the power and communication systems but also the gas, water, and electric railway systems. The underground cables of electric power companies are, of course, in common with telephone cables, susceptible to electrolytic injury, but such injury is usually caused by stray current from electric railways rather than from electric power distribution circuits.

General Survey

Problems, arising primarily from situations in which long power transmission lines and toll telephone lines parallel each other, assumed great importance about fifteen years ago, and led to the extensive studies of the Joint Committee on Inductive Interference in California.[4] Much of the work of that committee is fundamental to the present discussion. When the subject of the inductive relations of power distribution circuits and telephone circuits is set off as a topic in itself, it is not because the underlying principles are different from those which apply to the longer lines of the two services. It is rather the characteristics of the two systems in the thickly populated districts within and near the modern American city, and to some extent in rural districts, which give individuality to this problem.

While the primary concern is here with power distribution and local telephone circuits, nevertheless long

power transmission lines and telephone toll lines require consideration, if only indirectly, for in the final analysis these long circuits exist purely for the purpose of serving the public, and the sole links between them and the consumers are the local distribution systems. In the broad view, it is the public whose interest in the solution of these problems is fundamental. The vital importance to the two industries of finding the best engineering answer rests ultimately on this public interest.

In approaching the subject from a technical standpoint, perhaps the most convenient method of division is by reference to the physical relationships of the two utilities as determined by the character of the areas served. We may thus distinguish three general groups:

1. *Dense Urban or "Downtown" Districts.* In these localities which are principally in the larger cities, it is usual to find the circuits of both utilities in underground cable, carried, however, in separate conduit systems. There is, of course, a great deal of parallelism under these conditions in our large cities, from which, so far as the authors are aware, no cases of serious inductive effects have resulted, and except in rare instances, no physical damage has occurred. The problem of electrolysis has its chief focus in these districts but a discussion of this question is beyond the scope of this paper.

2. *Residential Urban Areas.* This term is used here to denote those districts in the smaller towns as well as the large cities in which the local telephone circuits are found mainly in aerial cable, with occasional fairly long runs of twisted pair or open wire, while the power circuits are chiefly in open wire. In the more thickly settled sections, long exposures at roadway separation or under joint-use conditions are common, and for shorter distances, in alleys, joint use or conflicting construction is frequent. Important questions arise here, both from the standpoint of physical hazard and from that of induction. The closeness of association and the large numbers of service connections involved, combined with the lack of the effective shielding afforded by cable sheaths and earth in the dense urban districts, make these residential urban areas the most important in respect to induction in the local telephone circuits.

Telephone toll circuits in these districts may be either in cable or in open wire. Owing to the relatively small numbers of such circuits and their limited space-occupancy, it is possible by suitable cooperative planning to keep them comparatively free of exposure.

3. *Rural Distribution Areas.* These are regions in which the population is scattered and the service drops of both utilities are relatively infrequent. Space is no longer a vitally essential factor, though it may still be an important one. Telephone toll circuits as well as subscribers' circuits are usually in open wire. These open-wire subscriber lines are likely to be long and to serve a considerable number of subscribers. By cooperative planning in advance, it is practicable to keep the telephone circuits comparatively free of exposure.

A large variety of power systems and voltages is found in different parts of the country, in the situations covered by these three broad classes. A classification on the basis of the purpose which the power circuit serves would give such groups as trunk circuits at voltages of 6600, 10,000 to 15,000, and higher, in both open wire and cable; primary distribution at voltages in the 2300 to 4600 range; secondary distribution at from 110 to 440 volts; and circuits for such services as street-lighting and street-railway power supply. Series street-lighting circuits are, under some conditions, of much importance as sources of interference and are discussed in another paper.[5] Railway circuits are also important from the point of view of inductive relations, but the discussion of their special characteristics is beyond the scope of this paper. Secondary-distribution circuits will come into the discussion in only an incidental way; the indications of experience are that interference from these low-voltage circuits is rare, though cases have been known to occur, due to accidental circuit conditions causing excessive currents in earth connections, or to unusual or poorly designed apparatus.

A classification along somewhat similar lines may be made of telephone circuits, having regard to the purposes to which the circuits are assigned. The subscribers' lines radiating from the central offices may be likened to the secondary power distribution circuits. Corresponding to the primary distribution system is the intricate network of trunks between central offices, used in local communication between subscribers in different exchanges. Other trunks, used in establishing connection between a subscriber and a toll center, when toll service is required, may be regarded as the counterparts of the higher voltage circuits. As the development of the art of power distribution has led to several kinds of arrangement such as direct-current, two-phase, three-phase and their varieties, so also in the telephone system, there are three main types of local circuit, according as the service is handled manually, or by the step-by-step type, or the panel type, of machine switching system. At present, in many of the large cities, the manual and one of the machine switching systems will both be found, together with systems of the intermediate semi-mechanical character, designed to give service between subscribers where one of the central offices is on a machine switching and the other on a manual basis. Many minor differences in equipment for signaling and supervision also exist, and there are several different arrangements of subscribers' sets and cord circuits, depending upon the type of service given; for example, individual line, or party line with full-selective or semi-selective signaling, with further differences according as the service is unlimited or on a measured basis, or according to the method of collection in the case of pay stations. In smaller communities, many other variations are encountered, including local battery arrangements with magneto ringing and sundry combinations of the local and common battery schemes.

Technical Features

Coupling and Shielding. A distinctive problem in the field of this paper is that of determining the coefficients of induction between power and telephone circuits under the conditions of close exposure that obtain in joint use and in conflicts. The fundamentally important work on this subject, done under the direction of the California Joint Committee, applies only to open wires at horizontal separations in excess of about

20 feet.‡ While the determination of the coefficients at closer distances is possible by calculation, (this method was used by the California Committee in their work at the wider separations), the labor required for the complete solution in the case of a large telephone line would be excessive. The experimental method is shorter and probably cheaper for these conditions and some experimental work is desirable in any event as a check. Such experimental determination is a part of the program of the Joint Development and Research Committee.

A power circuit having its conductors enclosed in a grounded metallic sheath will have very little external electric field, and if the currents are confined to the enclosed conductors and sheath there will be negligible external magnetic field. The result is the practical elimination of inductive coupling. It is only where part of the current returns by other paths than the sheath that induction results. While there are few data from direct experiment on the inductive effects of power circuits in cable, there is a great deal of evidence from operating experience in the case where both power and communication systems are underground, and a small amount where the power circuits are in aerial cable. This experience is based upon cables having all conductors in one sheath, and, under this condition, may be accepted as showing that inductive interference is rarely to be anticipated where the power system is entirely in underground cable with continuous metallic sheath. Experience to date with exposures in which the power circuits are in aerial cable with continuous metallic sheath, effectively grounded, justifies similar expectations. It might perhaps be thought that a breakdown of insulation with grounded sheath (either underground or aerial) would give rise to currents in the earth which would induce sizeable low-frequency voltages in closely exposed communication circuits. The absence of such occurrences in operating experience is probably due to the facts that a fault in a polyphase cable must usually involve all phases and that the sheath possesses fairly low resistance, thus tending to keep the fault current out of the earth. It is possible that the use of separate single-core cables for polyphase circuits may produce sufficient field to cause interference under certain conditions of proximity.

Both as to space occupied and shielding from induction, cabling the telephone conductors in metallic sheaths is advantageous. However, the magnetic fields, due to residual power currents and the "ground potential" effects, may be of great importance. If the cable sheath is continuous and is either underground or bonded to underground cable with an additional effective ground on the side of the exposure remote from the underground cable, the resultant electromagnetic shielding is of much value in reducing inductive effects. Where aerial cables are to be bonded to underground cables, however, careful attention to electrolysis conditions is required.

Another feature characteristic of inductive relations in distribution areas is that kind of coupling usually referred to as "ground potential." This term implies a difference in potential between two specified points in the earth. The term is convenient, but it should be understood that it does not connote a different kind of phenomenon from that where two grounded circuits are involved in a parallel exposure. The total voltage in a grounded circuit, a, due to current in another grounded circuit, b, (see Fig. 1) is produced in a distributed manner, partly in the metallic part of a and partly in the ground part of a. This latter part is, in general, the effect of both resistive and inductive coupling, and in practical cases its magnitude will depend almost entirely on the relative positions of the ground connections of a and b, and the route followed by the wire part of b. If, then, this part of the total voltage in a that is produced in the earth is considerably the larger part, the total voltage is frequently referred to as a

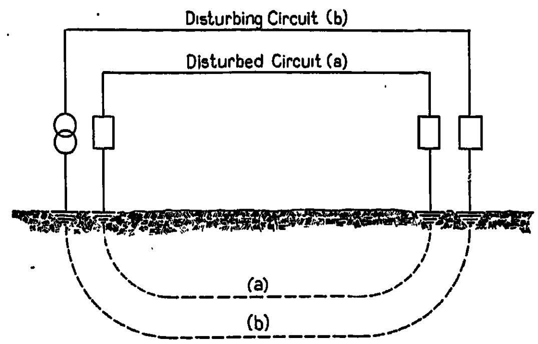

FIG. 1—GROUND-POTENTIAL
Inductive and Resistive Coupling

"ground potential." Used in this way, the term means simply that the effects observed are not due, to an important extent, to coupling involving the metallic part of the disturbed circuit a. Such situations, of course, are usually found where the amount of parallel exposure is relatively small.

The local telephone plant, particularly subscribers' lines radiating in all directions from a central office, is more likely to be affected by "ground potentials" than the toll plant. With some types of power distribution systems, the use of ground connections to the same water pipes or other underground structures as are used for telephone station ground connections has a tendency to increase these effects.

Owing to the numerous discontinuities of exposure that are inherent in distribution circuits, it is often impracticable to make effective use of transpositions of open-wire power or telephone circuits. The continual change of load connections and circuit layout in a growing plant tends to nullify a plan designed to fit a specific arrangement. There are, of course, exceptions to this, as in

‡. Refer to Item No. 4 of Bibliography, Technical Report No. 65.

long rural exposures where transpositions[6] are a suitable means of coordination.

Low-Frequency Induction Due to Transient Power System Conditions. Aside from questions of hazard through physical contact, the principal concern of the telephone engineer is usually noise, where the power-circuit voltage is not greater than 10,000 to 15,000 volts. For voltages higher than this, the effects of low-frequency induction under conditions of fault to ground on the power circuit are also important, often more serious than noise. It is quite possible that even with lower voltage circuits interference may arise under some conditions of transient disturbance. Operating experience, however, shows that such cases have been unusual.

With the higher voltage circuits, cases of serious trouble in exposed telephone circuits at times of power-system disturbance have been by no means uncommon. This is particularly true when the neutral is grounded, in which case the agency is magnetic induction due to current in the earth.

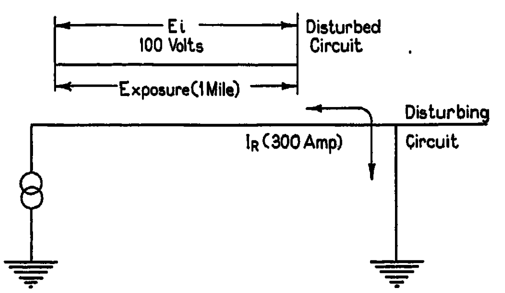

FIG. 2—MAGNETIC INDUCED VOLTAGE ALONG CONDUCTOR IN EXPOSURE AT HIGHWAY SEPARATION TO GROUND-RETURN CIRCUIT (AT 60 CYCLES)

To indicate the magnitude of this effect, it may be noted that the voltage induced between the ends of a conductor, paralleling at highway separation a circuit having ground as one side, is of the order of one volt for three ampere-miles of exposure, at 60 cycles per second. Thus, in the case shown in Fig. 2, with a fault current (I_R) of 300 amperes and an exposure one mile in length, the induced voltage (E_i) is about 100 volts. The value decreases less rapidly than the separation increases with change of separation up to several hundred feet§, and is, of course, dependent upon the current distribution in the earth. In the most favorable case the induced voltage is attenuated and appears as voltage to ground divided equally between the terminals of the disturbed circuit, but very often practically the full value of the induced voltage appears between conductors and ground at one terminal.

The forms in which this interference appears are substantially the same whether the exposed telephone plant is local or toll, *i. e.*, the induced low-frequency voltages may cause interference with telegraph and, if high enough, the operation of protective devices, false operation of signals (including subscribers' bells), acoustic or electric shock and damage to apparatus or equipment. These effects may be very serious and the development of generally satisfactory methods for their prevention is one of the outstanding problems confronting the engineers of the two industries. The work which has been done to date on this question has been called forth by the occurrence of more or less critical situations where relief by some means finally became a necessity to the telephone company. The measures which have been considered have ranged from removal of one circuit or the other to the use of resistance or reactance in the connections from power transformer neutrals to ground, and to the use of drainage on the telephone circuits. Good results have been secured in several cases where resistances in neutral ground connections have been installed. This was made practicable by the development of sensitive relays, arranged to operate on comparatively small residual (or ground) currents. However, there are situations in which the use of impedance in the neutral, no matter how large, cannot by itself afford a complete remedy. These are cases in which, even though the power neutral were isolated, the exposure is of such length and closeness that the voltages which would be induced electrically between the telephone wires and ground, when a fault occurs on the power system, are themselves sufficiently high, and the corresponding charges sufficiently great, to cause interference. An exposure of this character is most troublesome and any one who has had experience in attempting to deal with such a case would probably agree that all reasonable alternatives should be exhausted before such a condition is created.

The use of drainage on commercial telephone circuits for the relief of high-voltage induction, while not impossible, involves complications of operation and maintenance so great as to make it impracticable in the majority of cases. Drainage of the ordinary balanced retardation coil type cannot be used on any type of circuit employing d. c. signaling, and this excludes it at once from a large part of the class of circuits with which this paper is primarily concerned. Conditions under which drainage is feasible are most likely to be met on relatively short circuits where the induction is electric in character. This last condition means that few drainage coils, perhaps only one per circuit, would be required. Where the induction is magnetic and the induced voltages are not relatively small, difficulties are encountered in making drainage effective without causing excessive transmission loss or interference with signaling. The possibilities of drainage on telephone circuits as a measure for the reduction of interference are being considered in detail by the Joint Development and Research Committee.[2]

An apparatus for application in the telephone plant

§. For method of calculation, etc., see Item No. 4 of Bibliography, pp. 656 and 682. Taylor, Ref. 7, gives values that are low due to assuming current in earth returning very close to the surface.

known as the "acoustic shock reducer" is under development and is now being tried out in a few places. It is designed to reduce the intensity of acoustic shocks and is thus purely a specific remedy, without bearing on the several other kinds of important low-frequency interference. The trial installations now under study have been made at operators' switchboard positions. These devices must be regarded as expedients serving to alleviate, though not to eliminate, one of the most troublesome types of interference.

The provision of adequate separation between the power and telephone circuits, is, of course, the most effective remedy where it is feasible. Where the situation involves local service connections, separation is often not an available remedy, and there are other situations involving toll lines and power circuits where, owing to the nature of the terrain, separation of lines is, practically speaking, out of the question. These situations often present problems of very great difficulty.

Noise Induction. With the great variety of relationships, normal and accidental, which can exist between power distribution and telephone circuits, instances where noise interference occurs in the telephone circuits range from the heavy, low-toned rumble, caused by temporary contact of a 110-volt house service on a cable suspension strand, to the steady, high-pitched, single-frequency note sometimes found with apparently little exposure, coming from a grounded-neutral generator. It is not practicable to discuss here many very interesting but unusual cases. The great bulk, however, are found to be traceable to residual currents, and, in less degree, to residual voltages, in the power system. Induction from balanced voltages and currents is of importance, as a rule, only in exposures long enough to make practicable the use of transpositions as a means of relief.

It is well known that induction from residuals is much greater in proportion to the magnitudes of the inducing currents and voltages than that from balanced components. Some discussion of their origin and possible means of control is therefore given.

For convenience and clearness, and without intent to suggest a definition for more permanent use, the term "residual" is used in this paper to refer to voltages or currents that are residual with respect to all the metallic conductors properly belonging to the distribution circuit. In the case of a particular line, for instance, this includes the phase-wires and any associated neutral wire carried on the same poles. With cables, the sheath is included. It should not be overlooked, however, that voltages and currents in the circuit having the neutral as one side and the line wires as the other, are a distinct class, just as residual voltages and currents are distinct from those belonging to the line conductors only, and are likely to be characterized by large induction coefficients.

The situations of chief importance, in which residual currents and voltages exist in distribution circuits, are:

1. Along single-phase branches from polyphase circuits,
2. Where there are multiple grounds on neutral wires,
3. Where triple harmonics are introduced by grounding the neutrals of generators or transformer banks in three-phase circuits,
4. Where admittances to ground of the phase-wires are unequal.

To illustrate, consider Fig. 3, which shows a single-phase branch on a three-phase, four-wire circuit. This single-phase circuit is, of course, entirely unbalanced from a voltage standpoint. That is, the star voltage of supply is also very closely the residual voltage. If all three phases were present, there would be no such intrinsic residual voltage, but with only two phase-wires the effect is the same as with one. Not only at the higher voltages, such as 11,000 or 13,000, but also at the usual voltages of primary distribution, this residual voltage may give rise to serious noise in directly exposed open-wire telephone circuits.

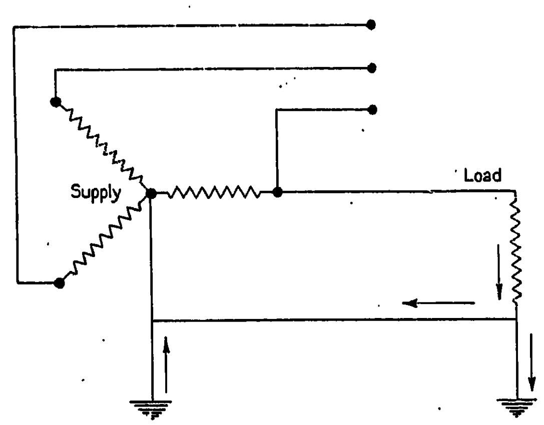

Fig. 3—Single-Phase Branch of Three-Phase Circuit

The amount of residual current in the case of Fig. 3, with neutral wire grounded at both ends, depends on the division of the load-current between the neutral wire and the earth, which is, of course, governed by their respective impedances. With the neutral grounded at only one point there is no residual current (neglecting capacitance to ground of the phase-wire). Were the neutral wire absent, the current would be entirely residual.

With all three phases present, the residual load-current will be reduced by balancing of the load among the phases, but with multiple grounds, there often remains ample residual load-current to cause interference. With only two phases present, equally loaded, the effect is the same as with one. It is a well established principle that the ground should not be used as a load-current path.

The arrangement illustrated in Fig. 3, with all phases present or with some of them lacking, may also give rise to triple harmonic residuals (item 3 above). The

presence of a single neutral ground causes the appearance of triple-harmonic residual voltages and charging currents. With one or more additional grounds, these residual currents are often much greater.

In some cases the system may be nominally grounded at only a single point, the additional grounds appearing more or less incidentally, as when the neutral wire is carried along as the sheath of a cable in sections where the circuit goes into underground or submarine cable. In other cases the system is designed to have multiple neutral grounds. An example is the three-phase, four-wire system in which a single wire serves as both the primary and secondary neutrals. This arrangement introduces a large number of grounds on the primary neutral because of the grounding at customer's premises or on the secondary side of transformers. It is the most difficult to deal with of all polyphase distribution systems employing a neutral wire. Owing to the impracticability of establishing and maintaining balance of loads, this arrangement results in residual load-current even when all phases are present in an exposure.

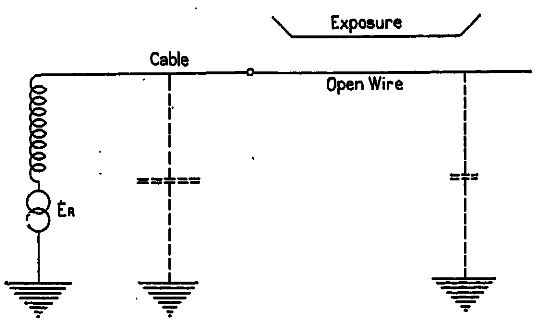

FIG. 4—EQUIVALENT CIRCUIT TO SHOW POSSIBILITIES OF RESONANCE OF TRIPLE-HARMONIC RESIDUALS IN THREE-PHASE, GROUNDED-NEUTRAL GENERATOR AND LINE

The distinctive difficulty is due to the residual current which as a rule contains both triple and non-triple harmonics.

Another type of situation involving triple-harmonic residuals which has recently appeared in several places, involves circuits at higher voltages. In these cases the power system is usually partly in cable and partly in open wire, with the generator connected directly or through auto-transformers to the cable plant. The generator neutrals and also those of the auto-transformers, where used, are directly grounded. In several particularly interesting cases, it appeared that a condition of resonance, or of an approach to resonance, existed at one of the frequencies of the triple-harmonic series between the direct capacitance to ground of the underground-cable system and the inductance of the generators or generators and transformers. The interference was not due to parallels with the underground cables, but in these instances appeared in circuits exposed to open-wire power circuits connected directly to the cables. The situation is sketched diagrammatically in Fig. 4 which shows the equivalent single-phase circuit of the three phases in parallel with "ground-return." It is to be observed that, with appreciable direct capacitance to ground beyond the exposure, the induction may be due to currents as well as voltages. Tests have indicated, in some of the cases which have been studied, that both types of induction were of importance.

A remarkable feature about one of these "resonance" cases was that the wave form of the generator voltage was unusually pure. Analyses of the generator voltage showed only a very small percentage of the particular harmonic (in this case the ninth) which was prominent in the noise in the telephone circuits—so prominent at one time that other frequencies could not be noticed on direct listening. The condition in which this harmonic was so strongly the dominating frequency in the noise passed with certain changes in the power system, although this frequency still continued as a prominent feature.

In another case, in which the evidence of resonance was less striking, the fifteenth harmonic was the dominant frequency in the noise, although the ninth and some of the upper triples were also present. The third harmonic was the strongest triple in the neutral current of the generator, accounting, in fact, for nearly all of the r. m. s. neutral current. The fifteenth harmonic was well marked in the line to neutral voltage of the machine. The telephone interference factor[8] of the neutral current wave was about 2000, in contrast with values of the order of 50 commonly found for load voltages and currents.

Another particularly interesting example, in which the power-circuit voltage was 13,000, involved an aerial power cable connecting at both ends to open wire and a telephone subscribers' cable, also aerial and at highway separation. The power cable went underground at one end of the exposure and tests showed that the interference, which was of severe character, was due to residual charging current, principally of the ninth harmonic frequency, which returned to the source of supply by way of the earth rather than along the sheath of the cable. This condition was due to the lack of an effective ground for the cable sheath between the exposure and the supply station. The case is of especial interest as illustrating the fact that shielding, even by metallic sheaths around both systems of conductors, may, in some cases, be quite ineffective, and also because it brings out the difficulties which may arise when dealing with induction from residual currents.

These cases and others resembling them have led to the application of various means of suppressing or reducing the magnitudes of the triple-harmonic residuals. A familiar and generally effective scheme is the provision of a grounding bank of transformers with a low-impedance delta and preferably the removal of the ground connection from the machine or transformers giving rise to the residuals. For effective results, such a bank should be designed for relatively

low magnetic flux density. Other methods which have been found effective involve the introduction of impedance in the connection from neutral to ground. This impedance may consist of a tuned circuit[9], where only a single harmonic is important, or it may consist of a simple reactor. In either case, its magnitude may be made small at the fundamental frequency. The Petersen reactor or earth-coil, in considerable use in Europe, is an effective appliance for the reduction of triple-harmonic residuals.[10]

When a circuit is designed to be isolated entirely from ground, residuals arise in it only through differences of admittance of the phases to ground. A common example is a single-phase tap on a three-phase line. The tap has residual voltage approximately equal to the star voltage to ground. In addition, it causes residual voltage on the main line. An isolating transformer to separate the branch from the main line prevents both effects. Serious induction has been experienced where tree grounds, defective insulation, etc., cause partial phase grounds. One ground, and sometimes more, may persist for long periods without affecting the power-circuit operation, meantime causing noise. Even high-frequency carrier current systems may be greatly affected by such intermittent ground connections.

Two-phase systems have characteristics in general

TABLE I

COMPARISON OF CERTAIN PRIMARY DISTRIBUTION SYSTEMS FROM STANDPOINT OF INDUCTIVE COORDINATION*

System				Residuals†				
				All Wires Present		One or Two Wires Missing		Facility of Coordination (all wires present)
No. of Phases	No. of Wires	No. of Grounds	Typical Diagram	Voltage	Current	Voltage	Current	
Single-Phase	1	Multiple		E	Total Load	..	..	Very difficult
	2	None		0	0	.	..	Good
	2	Single		E	Charging	..	..	Difficult—Residual voltage may be important
	2	Multiple		E	Part Load Plus Charging	E	Total Load	Difficult
Two-Phase	3	None		0	0	0.47 E or 0.75 E	0	Good
	4	None		0	0	..	..	Good—Identical with single-phase two-wire
	5	Single		0	Charging	0, E or $\sqrt{2}\ E$	Charging	Good
	5	Multiple		0	Part Load	0, E or $\sqrt{2}\ E$	Part Load and Charging	Difficult. Possible even harmonic residuals
Three-Phase	3	None		0	0	E	Charging	Good
	3	Single		Triple Frequency		E	Charging	Fair
	3	Multiple		Triple Frequency		E	Load	Difficult
	4	Single		Triple Frequency		E	Charging	Fairly Good
	4	Multiple		Triple Frequency and Part Load		E	Part Load and Triples	Difficult

*For high voltage three-phase systems factors not here considered may be important. (See text).

†Residuals arising from differences of admittance to ground, whether due to the configuration of conductors or to accidental leaks, are not included in the tabulation. By residual current is meant that part which is in the earth or in remote wire paths.

similar to the single- and three-phase systems just described. The two-phase, four-wire system with no connection between the phases or to ground amounts, in effect, to two independent single-phase systems. The problem of inductive coordination is thus reduced to the consideration of the effects of a single-phase circuit having no intrinsic residuals other than those due to line unbalances to ground which, for the voltages and lengths of circuit in common use, are negligible, providing, of course, that the line is maintained free of leaks to ground. This system is the simplest of all polyphase distribution systems to deal with, from the standpoint of inductive coordination.

The two-phase, three-wire system isolated from ground has no intrinsic residuals other than those due to line unbalances or to the omission of a conductor. The residual voltage, with one phase-wire lacking, is approximately 0.75 E (E being the voltage to neutral) while with the neutral lacking, it is 0.47 E. In at least one instance where a circuit, partly four-wire and partly three-wire, was operated as two-phase, three-wire by paralleling two wires in the four-wire portion, large admittance unbalance and induction resulted.

The two-phase, five-wire system, (really a four-phase symmetrical system), is similar to the three-phase, four-wire arrangement except that triple harmonics cannot appear as residuals, which is, of course, an advantage. If, however, even harmonics are present, the fourth and its integral multiples may appear as residuals, while the second and its odd integral multiples may appear in the metallic circuit, each side of which consists of two phase-wires in parallel. This system, with multiple neutral grounds, has essentially the same possibilities as the three-phase, four-wire system as regards residual currents due to load unbalances. The omission of two phase-wires of opposite phases causes no residuals. The omission of one or three produces a residual voltage equal to the star voltage.

To summarize this comparison of the various types of distribution circuit, Table I has been prepared to show the residuals encountered in thirteen different cases and the corresponding problem of coordination. Balanced currents and voltages are not included, as their treatment is much the same for the several systems described. The relative desirability of the several arrangements from the standpoint of power-system operation exclusively is not taken into account, and it is realized that the preferences indicated are doubtless not the same as would be arrived at by consideration from that point of view.

Although the paper is concerned primarily with a consideration of different kinds of power-distribution systems in an attempt to develop their characteristics which react on telephone circuits, (a point of view in keeping with a general discussion of power distribution, of which this paper forms a part), a brief statement relating the properties of the telephone plant to the problem may be helpful. This subject is being studied in detail by the Joint Subcommittee on Development and Research, previously mentioned.

The benefits and limitations of metallic cable sheaths for reducing the susceptiveness of telephone circuits have already been discussed. In cables, both local and toll, direct induction in the metallic circuit is negligible; noise appears in the metallic circuit as the result of the action, upon unbalances in lines or equipment,[11] of induction in "ground-circuits" (*i. e.*, circuits having the metallic circuit conductors as one side and ground as the other). These are self-unbalances to ground of the particular circuit under consideration, or unbalances between it and the other ground-circuits.

Telephone-line conductors, whether in cable or open wire, are designed to have the two sides of the circuit closely alike, so that the accidental unbalances inherent under actual construction and maintenance conditions are the only ones requiring consideration. Intricate transposition systems for open wire,[6] and elaborate arrangements for twisting cable pairs and splicing cable sections together, are examples of this design. Complete elimination of these accidental unbalances is, of course, impracticable.

In the cord circuits used in connecting subscribers together, there are small self-unbalances at the central office, but these are not sufficient to be a factor in the production of noise except in unusual cases of severe exposure. The necessity of guarding against noise and crosstalk from sources within the telephone plant involves many of the same considerations that are pertinent to this problem and has led to the limitation of these unbalances.

At subscribers' stations, there are unbalances due to grounded ringers on some types of party-line circuits and to coin-collect relays in some classes of service. Unbalances, due to ringers, may be reduced by the use of ringers of higher impedance than the standard, developed for this purpose, and some application of these higher impedance ringers has been made in working out specific cases of interference. Other possibilities for party-line stations exist, involving additional relays or other apparatus at the subscribers' stations.

Conclusion

1. The relationships of power distribution and telephone circuits are extremely intricate and varied, involving many considerations of the details of design of both systems. Both systems are expanding rapidly, having a common goal of universal nation-wide electric service.

2. The location, design, construction, operation, and maintenance of both systems require careful consideration from the standpoint of safeguarding properly the public, the employees, and the physical plant as well as suitable provisions for meeting present and future requirements for both services in an adequate and convenient manner.

3. Residual currents in power-distribution systems

are an outstanding source of inductive influence both at voice frequencies, and, under transient conditions, at the fundamental frequency. Under normal operating conditions, the limitation of residual currents appears to be largely a matter of the type of distribution system used. Under abnormal conditions, their limitation is a more difficult problem but still very much dependent on the type of distribution system.

4. With telephone toll-circuits, avoidance of severe exposure by choice of locations for both classes of lines is usually possible and the most satisfactory measure of prevention or mitigation.

5. The use of telephone cables with continuous metallic sheaths, grounded continuously or at terminals, is a very helpful measure.

6. Experience indicates that interference is not produced by exposures to power circuits in underground cable. The combination of underground cable in grounded-neutral systems with an open-wire power circuit in exposures has produced severe interference conditions in a number of cases. Aerial power cable with sheath adequately grounded is similar to underground cable from the standpoint of inductive effects but may give rise to interference if the sheath is not grounded in the proper manner.

7. A well-organized scheme of joint study and research covering the numerous engineering problems of coordination is in progress. While this study should result in the development of technical information of general applicability, the solution of existing interference problems is not attainable by any simple general rule, but only after careful analysis of the respective plants as actually constituted, to find the most practicable measures for relief applying to the specific case. Such solutions must be adequate to provide reasonable margins of flexibility in operation.

8. The design and construction of new plants for both classes of service, and the choice of measures of relief in existing cases, should be guided by a sense of common responsibility to insure successful coordination in the period of great growth that is anticipated. To this end, the exchange of information and joint planning by power and telephone engineers, in advance of the crystallization of designs, is obviously the only practicable method of handling the problem.

Discussion

H. S. Phelps: Messrs. Trueblood and Cone have very ably and clearly pointed out the importance of the type of power-distribution system in the matter of inductive coordination. This importance is recognized, and as the problem is better understood, more and more attention is being given it. It seems to me, however, that they have not placed sufficient stress upon another equally important feature—namely, the characteristics of the telephone system.

The ideal arrangement, of course, would be, first, a power system without residual currents or voltages, with the conductors very close together; such a system would be closely approached by using multi-conductor cable, where all the current was forced to return in the conductors; second, a telephone system without any impedance unbalance in the metallic circuit or admittance unbalance between the two sides of the circuit to ground. In this desirable telephone system the subscriber's set should not require utilization of an unbalanced ground connection for ringing. Connecting such an instrument to the system by means of a well designed and carefully installed cable circuit to a well balanced central-office cord circuit would likewise materially improve the situation.

An ideal power system would not produce longitudinal voltage in neighboring telephone circuits, and therefore could not cause noise in the telephone system, regardless of telephone circuit unbalances. On the other hand, an ideal telephone plant would not be susceptible to induced longitudinal voltages, and therefore could not be affected by any distribution system during normal or abnormal conditions, unless the induced voltages were of a magnitude to constitute danger to life or property.

Since neither ideal system is necessary or practical, it remains to determine how far either system may depart from the ideal without placing serious limitations and burden on the other. In order to ascertain the technical facts underlying this problem, the joint Development and Research Committee of the National Electric Light Association and American Telephone and Telegraph Company has been carrying on work under one of its projects at Minneapolis for over a year.

Although many interesting and useful results have been obtained, it would be premature to attempt outlining any of these at this time. However, it is expected that an interim report will be issued in the early spring covering the major findings of this work.

The considerations outlined for coordination of the telephone circuits with a distribution system apply in the same manner to

the problem of induction from a lighting system discussed in the paper by R. G. McCurdy.[1]

P. D. Jennings: I gather from reading this paper and from an informal talk with Mr. Cone that the residual higher harmonic currents are the ones that give the most trouble. I should like to ask why resonance shielding on substation ground circuits might not take care of most of this trouble. As an example, suppose in a particular substation, our oscillograph records show that the ninth and fifteenth harmonics are predominant. It occurred to me that a resonant shield might be used to resonate out the ninth and the fifteenth harmonics on the substation ground and in that way eliminate most of the trouble.

A. A. Williamson: Mr. Cone referred to the relatively greater freedom from inductive interference that is usually experienced when both the power and the telephone circuits are in cable. Cases sometimes arise, however, where interference is experienced between the two classes of circuits when they are both in cable, and such cases are usually of somewhat more than ordinary interest. A very brief reference is made to such a case in the paper and it seems to me that a few words of additional description of the conditions in that case would be interesting.

In this instance, power at 13,000 volts was supplied directly by a three-phase generator, connected in Y and with the neutral grounded, to two open-wire circuits, branching and each supplying 13,000-volt power to a substation. The power company decided to provide a tie between the two substations and concluded that in this case the tie should be of cable. The tie when installed was approximately 1.65 mi. in aerial cable, and about 0.7 mi. in underground cable. The sheath of the underground cable was, of course, well grounded, but was not connected in any way to the neutral of the generators. This cable tie paralleled in its aerial portion an aerial telephone cable.

As soon as the tie was energized, interference was noted in the telephone circuits. An investigation showed that the sheath of the aerial power cable was also grounded at intervals with driven grounds but that these grounds were of rather high resistance so that the residual charging current flowing into the cable sought ground and returned to the generating station through the low-resistance ground afforded by the sheath of the underground portion of the cable. Thus the charging current flowed through the parallel as residual current and produced interference. By installing a low-resistance ground on the sheath of the aerial portion of the power cable, at the end more remote from the underground portion, the induction was very greatly reduced. The reason for this was that with the additional ground in place, the charging current flowed through the capacity of the wires to the sheath and back over the sheath. Thus, in each part of the parallel, there was a return path for the charging current flowing out over the three-phase wires and instead of acting as a residual current, it became a balanced component. This case illustrates the effect of residual current in causing induction sometimes of serious magnitude even when both classes of circuit are in cable.

I should like also to cite very briefly a case with which I happen to have had intimate contact on the Atlantic Seaboard. This case illustrates the importance on the induction problem of unbalanced load current flowing in the ground. In this instance, a 4000-volt, three-phase, four-wire distribution system with the neutral grounded at the point of supply paralleled in open-wire construction an aerial telephone cable. The parallel was about 8000 ft. in length; it was joint construction and at the end of the parallel more remote from the point of supply to the power system, the three-phase, four-wire circuit entered underground power cable. At that point, the neutral wire of the three-phase, four-wire system was connected to the underground cable sheath. As the sheath of the underground cable was well grounded, it could be seen that any current in the neutral due to unbalance of load between the three phases would return to the power station both by way of the neutral and by way of the ground, the division of current in the two paths being in approximately inverse proportion to the impedance of these two paths.

In this case, measurements were made of the interference on party line subscribers' circuits in the telephone cable, and approximately 900 standard noise units were found at the subscribers' receivers. Owing to the excellent cooperation of the power company in this case, it was possible during the investigation to disconnect temporarily the power cable from the aerial portion. When this was done, the path for the unbalanced load current to return through the ground no longer existed. Under this condition the induction was reduced to about one-third of its former value.

This case seems to illustrate very well the effect of unbalanced load current when it can return through the ground. The use of power cable with the sheath connected to the neutral wire is only one of the ways in which a path may be provided for unbalanced load current to return through the ground. Whenever the neutral wire of a three-phase, four-wire system is grounded at several points, this same opportunity exists and experience has indicated that it is usually one of the most important features from an induction standpoint.

K. L. Wilkinson: In practically all cases telephone subscribers are users of electric light and power service. Therefore, the companies, in order to serve these customers in distribution areas, must of necessity have their overhead lines in close proximity to each other. The problems arising therefrom are mutual ones since they involve the rendering of both services to these common customers in a safe, adequate, and economical manner. It seems to be now generally appreciated that these problems require cooperative consideration by the two utilities in order to be successfully solved. The advantages of this cooperative treatment have generally been recognized throughout the country, and the splendid cooperation between the operating utilities in the field is producing most satisfactory results.

Now, in order that these individual efforts in the field may be most successful, it is desirable that all parts of the country know what is going on in all other parts of the country and be in a position to have made available to them all of the data and information which would shed any useful light on the problem. To this end, some four years ago there was organized the Joint General Committee of the National Electric Light Association and the Bell Telephone System. This Committee was to investigate the physical relations between electric supply lines and communication lines, and to develop principles and practises for the guidance of the operating companies in solving their day-by-day problems.

The Joint General Committee has at its disposal all the operating experience of the country and has, as you know, published *Principles and Practises for Inductive Coordination of Supply and Communication Systems.*

The principles which have been developed are nothing new; they are based on the operating experience in their day-by-day work in coordination of the two systems.

One of the most important, I think, is the principle of cooperation and the advance notice. I thought of that particularly when Mr. Heinze mentioned the growth and development of the power systems in the distribution areas, the increasing load density and the fact that nearly everybody now has a telephone and every telephone must be a part of a system that operates throughout the United States, so that any one telephone in any one part of the country can be connected with any other telephone in the system.

If we are going to have the best and most economical power system to supply the people with electric light and power, and if we are to achieve the ideal of universal communication throughout the country, it is absolutely essential that locally and nationally we establish and maintain the closest contact

1. Induction from Street-Lighting Circuits, by R. G. McCurdy, A.I.E.E. JOURNAL, Vol. XLIV, October, 1925, p. 1088.

between the two utilities in order that the public may obtain the fullest benefits of all of our engineering knowledge and experience.

The Joint General Committee, in approaching the problem, established one thing clearly and that was that each party should be the judge of his own service requirements and what was necessary to serve his customers. Next to that was the duty of coordination; that is, each party should so conduct his business as to be less productive of adverse influence on the other system; and, the system should be as free as practicable from things which would make it capable of being adversely affected.

I think that if we bear these major thoughts in mind,—first, that each is the judge of his own service requirements, and second, that we have a mutual duty toward the public to see that they get safe, adequate, and economical service,—then the necessity of planning well in advance so that the situation does not get out of hand will be fully appreciated and we shall be promoting the best interests of the public in getting these two necessary services.

F. O. McMillan: Would it not be advisable to include in this paper under the three-phase transformer connections, some reference to both the primary and secondary winding connections, because of the fact that the third-harmonic magnetizing current and all multiples of the third harmonic in Y-delta-connected transformers are very nicely cared for when the delta connection is used on either side of the transformer?

S. B. Hood: In the paper I note, in the tabulation of the relative ease of coordination of the different systems, that almost without exception, the power system which is easiest to coordinate is the very system which the power man does not want to use.

Now that means that we must have a cooperative spirit of give and take. At some place in the list is the system which is just as good for the telephone man as for the power man. Just where it is, I don't know. I don't think it has ever been discovered, but we certainly have to work in a true cooperative spirit toward that end.

M. T. Crawford: Mr. Cone refers to the possibility of a slight ground which persists for some length of time as being a very serious source of interference when it occurs on the primary system.

I believe that practical experience will bear me out that on a grounded-neutral primary system it is almost impossible for a slight ground to persist for any great length of time. The ground on the grounded-neutral system is a short circuit and very soon develops into something that will trip the switch out. That would be an argument in favor of the grounded-neutral system as being superior from the point of telephone interference.

I should like to ask Mr. Cone what he considers the principal objection to raising somewhat the 5000-volt limitation which is at present observed in connection with joint-pole construction of light-and-power and communication circuits. This, of course, is an old question, but it seems today to assume a new aspect inasmuch as there is here evident such a willingness to cooperate. Perhaps the difficulties of joint-pole construction on voltages over 5000 have been where the distribution work of the light and power companies was not planned far enough in advance to take into account the telephone company problem.

The Puget Sound Power and Light Company now operates on a part of its system a commercial telephone system which was taken over in connection with the purchase of a smaller company. On this system we have 6600-volt primary distribution on our own poles in combination with our own telephone service lines. We have been able to live very well with ourselves under such conditions.

L. J. Corbett: I wish to second Mr. Hood's remarks in regard to cooperation in spite of the suggestion which has been made that a wave of propaganda is upon us.

I have observed that the telephone men have studied the theoretical part of power transmission and distribution rather thoroughly. But very few power men study the telephone problems thoroughly. If we did and suggested to the telephone companies how to operate their systems, it might be taken in the same spirit as that in which the power men receive suggestions from the telephone men as to how they might operate their systems.

The ideal manner of handling the inductive-coordination problem would be realized if the same interests owned both the communication system and the power system. If this were true they would be compelled to get together and determine the accurate economic solution in each case.

In California we act under the California Railroad Commission. The order of the commission is a state law, and under that law we are "required to cooperate." We find that this cooperation really works both ways. It is not always merely doing that which is requested by the telephone company; we do a little telephone engineering ourselves, although not in a very aggressive way. When the telephone company suggests coordinating measures, as a rule we put them in when it is possible without unreasonable expense.

If, from our standpoint, they do not appear reasonable, or if some construction or operating difficulty is involved, or a higher unjustifiable expense is indicated, we raise the question as to whether or not the benefits to be gained by these measures are worth the expense and trouble involved. When such communications reach telephone company officials, the requests are usually modified or dropped.

The beauty of the California law is that public interest comes first, and the cost of any of these coordinating measures is reflected in the rate. In this manner the public is the final unifying agent or manager and the holder of the purse-strings.

F. H. Mayer: Mr. Cone raised some objection to the grounding of the neutral return on 4-kv. distribution systems. It is the practise of the Southern California Edison Company to ground the neutral at numerous points throughout the distribution system to enable the secondary voltage to remain somewhere near a safe value should the return cable become broken. The driven pipes will tend to span the gap and thus prevent the Y connection from straightening out to a straight delta connection. If the loads on the different phases are carefully balanced there ought not be any communication disturbances.

H. M. Trueblood: I am sure we can all endorse the attitude expressed in Mr. Phelps' discussion, namely, that the solution of the problem consists essentially in finding the degree to which ideal systems must be approximated.

Mr. Phelps' reference to the joint investigation at Minneapolis should, I feel, include mention of the Northern States Power Company and the Northwestern Bell Telephone Company as participants. The progress which has been made in that work is due in no small degree to the effective cooperation and assistance of these two companies.

As regards the suggestion that the paper does not lay sufficient stress on the characteristics of the telephone system, I wish to say that there is no desire to ignore this phase of the problem. The paper has been presented as one of a group dealing with various aspects of power distribution and, as such, it does not purport to discuss telephone-system characteristics except incidentally.

With reference to Mr. Jennings' inquiry, I know of at least one case in which the measure which I believe he has in mind was applied successfully. In this instance, there were two harmonics to be taken care of, the 15th and the 33rd, and two antiresonant elements, each consisting of a condenser and an inductance in parallel, tuned respectively to the frequencies of these two harmonics. They were connected in series between the neutral

of a 13,000-volt generator and a grid resistance of low value, the other terminal of which was grounded. The exposure involved was about 3 mi. long at a separation of some 30 ft. I have been informed that effective reductions were obtained in the noise, previously quite severe, and that the arrangement has proved satisfactory from a power-operating standpoint.

Mr. McMillan refers to the omission of reference to the effects of delta windings. Because of the rather extensive ground covered in Table I, it was necessary to simplify the table and to make some selection among the different features that might be included. Of course, delta windings on transformers do affect the magnitudes of the triple-harmonic voltages and currents that appear on the lines; but this effect may be either to increase or to diminish the magnitudes of the line residuals of these frequencies, depending upon the locations of the transformers concerned and the conditions of grounding. Of the systems summarized in the table, those presenting the greatest difficulties in coordination are ones in which the load currents are more important than excitation currents, and, of course, the transformer connections are immaterial, so far as load currents are concerned.

Mr. Hood and others have remarked that the distribution systems classified in the paper as presenting the greatest facility of coordination are not those which a power company would ordinarily adopt if nothing more than the distribution of power were involved. Without attempting to pass judgment on the relative merits of different systems from the latter standpoint, I believe we should not be surprised that a conflict of this character is found to exist. This is an essential feature of the situation with which we are confronted at the present time. In fact, we have an inductive-coordination problem largely because types of systems which are deemed advantageous from one standpoint may not be so from the other. Mr. Hood's inference from the situation to which he refers is substantially the same as that arrived at by Mr. Phelps, and I find no difficulty in concurring in it.

Mr. Hood has referred to the use of multiple grounds on the neutral as a stabilization proposition. While stabilization may be the principal purpose in using the multiple-grounded neutral, it is unfortunately true that this does not prevent the setting up of residual load currents.

In his remarks applying to Mr. McCurdy's paper, as well as to that by Mr. Cone and myself, Mr. Heinze refers to the question of cooperation between the telephone company and the other electric utilities. It is true that most telephone engineers who have had to do with the inductive-coordination problem keep prominently before them the idea of cooperation. That is because it appears to us that no other method of approach can be successful. While this is more nearly self-evident now than it was some years ago, it is so important that one feels justified in laying stress upon the idea. The same thought has been expressed more than once by power engineers in the discussion of these papers.

Mr. Heinze asks how far the telephone company will go in this cooperative endeavor. As to the general spirit and attitude of the Bell System, I will merely remind you that for a number of years it has gone to considerable trouble and expense to adapt itself to circumstances which have arisen because of situations of proximity between its circuits and power circuits. That this willingness to cooperate in the fullest way will be maintained in the future seems to be sufficiently evidenced by the adoption of principles and practises by the Bell System and the N. E. L. A., under which cases are now being handled generally throughout the country, and by the undertaking of a joint research investigation to determine the fundamental physical and engineering factors which enter into the inductive-coordination problem. The work at Minneapolis is one project in this general research program, and other projects are under way in different parts of the country. As to division of cost, it must be recognized that after the correct engineering solution of a given case has been found, the question of an equitable division of the expenditure necessary to put it into effect will arise. This phase of the problem has so many ramifications that any attempt to summarize it here might be misleading, and a comprehensive discussion would carry us much beyond the field with which the paper is concerned.

In conclusion, I wish to make it clear that Mr. Cone and myself have attempted nothing more than to analyze the problem in a preliminary way without going into detail, and to bring out the technical facts known to us as we see them. Mr. McCurdy, I am sure, would agree with this attitude.

D. I. Cone: Mr. Crawford spoke of the interference that arises from accidental grounding of one phase wire. On a three-wire system normally isolated from ground, such conditions may persist for days at a time, or longer. This can be prevented by suitable maintenance measures. On the other hand with the grounded-neutral system the tendency is for such accidental contacts to develop into short circuits and to operate the circuit breakers. From the discussion by Messrs. Crawford and Cunningham it is evident that the local conditions immediately surrounding an accidental ground contact cause great variations in contact resistance and resulting ground current.

Mr. Crawford has raised the question of joint use at higher voltages than have been customary in the past. Many of you are doubtless aware that the subject of conditions of joint use is under active study by the Joint General Committee of the N. E. L. A. and the Bell Telephone System. We do, of course, recognize that there are some special cases where joint use of poles at higher voltages is the best engineering solution to meet the conditions of a particular problem and in such cases joint use is being approved.

Mr. Crawford also stated that his company had lately acquired a combination power and telephone distribution system with the power lines operating at 6600 volts. Our experience has not been encouraging as to the conditions of noise and hazard that obtain in such circumstances.

There are, of course, differences of opinion in respect to the question of protection from the hazards of power distribution. I wish to suggest, first, that higher voltages are ordinarily employed in distribution for longer distances and larger loads and, second, that this inevitably means either extraordinary measures to prevent hazard and impairment of service or else lowered standards. It is our view that advance planning will enable us to avoid to a great extent the necessity of joint use at the higher voltages. Meanwhile, any specific situation that arises we are more than ready to consider.

Mr. Corbett has described the working out of cooperative consideration of specific cases in California. As he states, the best results are obtained when the reactions of proposed measures are thoroughly considered by both parties. Suggestions arising from the study of these problems by the power engineers are cordially welcomed. I think it fair to say that the working together in California is not merely a matter of compliance with regulations but a realization that it is the rational way for the power and communication utilities to solve these problems. Mr. Mayer's discussion brings out the fact that there are conflicts to be adjusted between the requirements of the communication and power distributions and that the degree of detriment from multiple grounding depends upon several factors in the layout of the systems. Mr. Mayer's point about the use of multiple grounds on the primary neutral for stabilization has also been brought out by Mr. Hood. While recognizing that accurate balance of loads might prevent detrimental induction in communication circuits so long as all phases are present, we must not overlook the facts that setting up and continuously maintaining such close balance is not a simple matter and that exposures often occur where only one- or two-phase wires are involved.

Induction from Street Lighting Circuits

Effects on Telephone Circuits

BY R. G. McCURDY[1]
Associate, A. I. E. E.

Synopsis.—This paper discusses series street lighting circuits from the point of view of their relations to nearby telephone circuits. These lighting circuits often have a much greater inductive influence in proportion to the amount of power transmitted than have most other types of power distribution or transmission circuits. This is due to the relatively large distortion in wave shape of voltage and current on certain types of these lighting circuits, and to the unbalanced voltages to ground which occur with series layouts. Three general types of lighting circuits are discussed. These are a-c. arc circuits, d-c. arc circuits supplied by mercury arc rectifiers, and alternating-current incandescent circuits. Of these, the incandescent type of circuit, in which the lamps are equipped with individual series transformers or auto-transformers, is the most important in this respect. Measures for reducing interference from these circuits are discussed. It is hoped that the information given in the paper will be useful to power and telephone engineers in their cooperative efforts to solve these difficulties.

* * * * *

INTRODUCTION

INDUCTIVE interference from series street-lighting circuits was one of the first interference problems which confronted the telephone engineer and arose very early in the development of the power and telephone industries. Then, as now, these lighting circuits contributed a much larger amount of interference to exposed telephone circuits in proportion to the amount of power transmitted than most other types of power distribution[2] or transmission circuits. This is due to the relatively large distortion in wave shape of voltage and current on certain types of these lighting circuits, and to the unbalanced voltages to ground which occur with series layouts. Exposures of telephone circuits to this type of power circuit occur more frequently in or near towns which are naturally the terminals or repeater points of toll telephone circuits, which tends to emphasize the importance of this kind of exposure. Moreover, these exposures are often irregular, the layouts being frequently changed due to adding and removing lamps, which makes it difficult, and often impracticable, to coordinate transpositions in the lighting and telephone circuits, a remedy commonly employed in other types of inductive exposure.

Three types of series-lighting circuit are of interest in this problem and are discussed in detail later in the paper. These are a-c. arc circuits, d-c. arc circuits supplied by mercury arc rectifiers and a-c. incandescent circuits. The last type of circuit may also be divided into two classes in one of which the lamp filaments are metallically in series with the line and the second in which they are connected to the secondaries of individual series transformers or auto-transformers. In the straight series circuit the lamps are bridged by film cut-outs which break down and close the circuit when the lamp fails; in the individual transformer or auto-transformer type the transformer is usually operated with open-circuited secondary in case of lamp failure. High-current lamps of the higher candle-power ratings are normally used in connection with the individual transformer type of circuit.

The a-c. arc is now practically obsolete and very few installations remain. In the present state of the art, the d-c. arc and the high candle-power incandescent circuits with individual transformers are used mainly for high-intensity "white-way" lighting in downtown districts, where both the supply and telephone circuits are in cable. Lighting circuits in the outlying districts of cities where both the lighting and telephone circuits are of open-wire construction are more often of the straight series incandescent type. This is a fortunate circumstance with respect to inductive interference which will be apparent from the detailed discussion of the characteristics of the various systems. However, a serious problem is presented by the number of cases which occur where both the lighting and telephone circuits are in open-wire and the lighting circuits are either of the arc lamp type supplied by mercury arc rectifiers, or of the incandescent-lamp type equipped with individual transformers. As the general trend of development is toward the use of higher intensities and toward the extension of highway lighting, the importance of the problem seems to be increasing.

While there are a few cases in which these series circuits are supplied directly from constant potential sources, as a rule a constant-current regulating transformer or regulating reactor is used to maintain a constant current, the terminal voltage varying with the load. The reactance of this transformer is normally large as compared to an ordinary constant potential transformer, particularly when the circuit is only partly loaded, which is often the case in order to provide for flexibility and growth. The reactance of this regulating transformer has an important effect on the wave shapes in the a-c. circuits.

In the discussion which follows, the different types

2. A discussion of the inductive effects of distribution circuits generally is given in a paper, "Power Distribution and Telephone Circuits—Induction and Physical Relations," by H. M. Trueblood and D. I. Cone; see page 1052.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

of circuit are treated separately. Multiple street-lighting systems are not discussed in this paper as it is considered that the problems involved are not materially different from those arising with other multiple lighting systems.

A-C. Arc Circuits

Distortion of wave-shape in a-c. arc circuits is chiefly due to the non-linear characteristics of the arc.[3] On account of the high reactance of the constant-current regulator, the current wave is maintained approximately sinusoidal. Every time the current wave passes through zero, it is necessary for the voltage to build up in order to reestablish the arc; the voltage then decreases as the current increases to its maximum. The voltage again increases as the current decreases, a second maximum of voltage being reached just before the current passes through zero. The voltage wave thus contains two peaks in each half wave occurring immediately before and after the current goes through zero. As a result, the voltage wave on the circuit contains a complete series of odd harmonics, the magnitudes decreasing with increasing order but continuing large within the voice-frequency range.

Each lamp on the circuit contributes to the distortion. If the lamps are distributed approximately uniformly along the circuit, the harmonic voltages to ground at the regulator terminals will be equal and opposite, and the voltage to ground at the middle of the circuit will be zero. Aside from the length and other physical dimensions of the exposure, it is evident that the magnitude of the induced effects will depend upon whether or not both wires of the lighting circuit are present, the total voltage of the circuit, and the location of the exposed section with respect to the terminals of the lighting circuit.

If the exposure involves only one wire of the lighting circuit near either of its terminals, the induced effects are liable to be severe; if near the middle of the circuit, the effects are relatively smaller. If two sides of the circuit are present, the voltages to ground are equal and opposite provided an equal length of wire and an equal number of lamps are in each side within the exposed section and between the exposed section and the constant-current regulator. The magnitude of the harmonic voltages between the two wires depends upon the number of lamps beyond the exposed section. With such symmetrical lamp circuit layouts it is generally practicable to reduce the induced disturbances to tolerable magnitudes by means of transpositions in both lines, provided the separation is not less than the width of a highway. Since each lamp contributes to the disturbance, lamps occurring within the exposed section must be treated as discontinuities. This makes coordination difficult, particularly if the number of telephone circuits is large. Such an arrangement also makes for inflexibility in the lighting circuits, as in adding or removing lamps the symmetrical arrangement must be maintained.

Another method of coordination which is more satisfactory when conditions permit its application, is the use of a series transformer to isolate the exposed section from the remainder of the circuit. The harmonic voltages acting on the exposed section will then be only those due to the lamps on the secondary of the series transformer and dissymmetry on the primary side will not contribute to the induction. The symmetrical layout need then be applied only to the secondary side. Replacing the arc lamps on the series transformer secondary with incandescent lamps without individual transformers and equipped with film cutouts, constitutes an effective remedy.

With open-wire lines it is generally difficult, at highway separations, to reduce the noise to tolerable magnitudes unless the exposures are short. Under joint use conditions it is ordinarily impracticable to reduce the noise satisfactorily without replacing all or part of the arc lamps. It is fortunate, therefore, that the use of the a-c. arc lamp for street lighting is rapidly disappearing.

D-C. Arc Circuits

Distortion of wave-shape in d-c. arc circuits is principally due to the characteristics of the mercury arc rectifier.[4] As there are no reversals of current through the arc lamps and the changes in line current are comparatively small, changes in the resistance of the lamp arcs with change in current have a practically negligible effect in causing wave-shape distortion. The voltage and current waves set up by the rectifier contain a ripple of double the frequency of the a-c. supply with single-phase rectifiers and of six times the a-c. supply with three-phase rectifiers. Odd and even harmonic frequencies of this fundamental ripple are also present.

In order to maintain the arc, a sustaining reactance is required in the single-phase rectifier. This reactance damps out the ripple and its harmonics to a large extent. If the lighting circuit contains an appreciable length of cable between the rectifier and the open-wire section, the harmonics will be still further reduced.

Since the harmonic voltages and currents are impressed at the lighting-circuit terminals, if the lamps are distributed uniformly around the circuit, the harmonic voltages to ground at the circuit terminals will be equal and opposite and the voltage to ground will be zero at the middle of the circuit. The voltage distribution is thus the same as with the a-c. arc circuit.

The discussion given above in connection with the a-c. arc circuit of symmetrical layouts and two-wire circuits within exposures applies also to the d-c. arc

4. Steinmetz: "Transient Phenomena and Oscillations," pages 264 and 265.

circuit, except that the series transformer cannot be used and that symmetry must therefore extend through the whole circuit.

While the wave-shape distortion in these circuits is less serious than in a-c. arc circuits, coordination is very difficult when the exposures are severe, as when open-wire lines are joint.

A-C. Circuits with Straight Series Incandescent Lamps

If it were not for the distortion in lamps and associated equipment the wave-shape of any series a-c. circuit, regulated for constant current, would be better than that of the constant potential source from which it is supplied. This is due to the reactance of the constant current regulator which interposes a high impedance to the harmonics in the constant-potential supply. With straight series incandescent lamps this condition is substantially realized. While the resistance of the filaments changes with the temperature and thus with the current, the changes within a cycle are very small and the resulting distortion is negligible. A number of instances have been noted[5] where the telephone interference factors of the voltage waves of such circuits were from one-fourth to one-half the factors of the constant-potential supply sources.

Unless rather severe exposures with single-wire lighting circuits are involved or the telephone interference factor of the constant-potential supply is very high, induction into telephone circuits from circuits of this type is small. Where induction does exist it is usually practicable, by revising the circuit layout as discussed in connection with the a-c. arc circuit, to reduce the voltage to ground. Obviously the departure from symmetry of layout can be much greater for a given exposure than for either type of arc circuit.

A-C. Circuits with Incandescent Lamps Individually Equipped with Series Transformers, Auto-transformers or Bridged Reactance Coils

Under normal conditions, with all lamps in service, this type of circuit, from the induction standpoint, is practically the equivalent of the straight series circuit discussed above. Harmonic exciting currents required for either the individual transformers, auto-transformers, or bridged reactance coils are largely supplied by the local circuits through the lamp filaments. Important wave-shape distortion in this type of circuit occurs only when the secondary circuit of the individual transformer opens due to failure of the lamp filament. When the secondary circuit opens, the full line current becomes exciting current in the primary, greatly over-exciting the core. Because of the high impedance of the series circuit including the reactance of the constant-current regulator, the line current remains approximately sinusoidal. Practically the full amount of the harmonic voltage generated by the individual transformer appears across the terminals of the constant-current regulator.

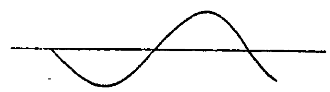

Fig. 1—Current in Transformer Primary 6.6 Amperes

Figs. 1, 2 and 3 show tracings of the voltage and current waves of one of these individual auto-transformers. Fig. 1 shows the line current in the primary

*Indicates a value of 0.5 volts or less.

The effect of the one individual transformer, with open-circuited secondary, in increasing the harmonic voltages and the telephone-interference factor of the voltage wave of the circuit, is evident. The presence of other transformers with open secondaries increases the harmonic voltages slightly less than in direct proportion. That the increase is not linear is undoubtedly due to the effect of the small harmonic charging currents and to changes in phase of the harmonic voltages along the circuit from one individual transformer to another.

In respect to the distribution of the harmonic voltages around the circuit, an important distinction is to be made between the a-c. circuit with incandescent lamps equipped with individual transformers and the two types of arc circuit discussed above. In the arc circuits, the distribution of harmonic voltage is fixed and the voltages to ground on the exposed section remain the same as long as the circuit layout is unaltered. With this incandescent lamp circuit the harmonic voltage to ground depends both upon the number of individual transformers having open secondary circuits and upon their locations.

In discussing the effects of "out-lamps" at different locations along the circuit, it is convenient to replace the transformer by an equivalent generator with terminal voltage, e, of complex wave form and equal to the harmonic voltage drop caused in the circuit by the transformer with rated line current in the primary and with the secondary open. The impedance of the constant-current regulator at the harmonic frequencies involved is high compared to the impedance of the line and of the individual transformers having closed secondary circuits. Hence, the actual circuit may be replaced by the equivalent circuit shown in Fig. 4.

In this figure, e represents the generator equivalent to the individual transformer with open secondary. The capacitances C_{1g} and C_{2g} represent the capacitances to ground of the two wires of the circuit between this individual transformer and the constant-current regulator. It is evident that the relative values of C_{1g} and C_{2g} will vary with the position of the individual

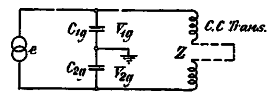

FIG. 4

transformer along the circuit, but that the sum of the two capacitances (the total capacitance to ground of the circuit) will be a constant. Letting V_{1g} indicate the voltage to ground of the section of wire having the capacitance C_{1g}, and V_{2g}, the voltage to ground of the section having the capacitance C_{2g},

$$V_{1g} = e\frac{C_{2g}}{C_{1g} + C_{2g}}$$

$$V_{2g} = -e\frac{C_{1g}}{C_{1g} + C_{2g}}$$

$$V_{1g} - V_{2g} = e$$

$$V_{1g} + V_{2g} = e\frac{C_{2g} - C_{1g}}{C_{1g} + C_{2g}}$$

If the construction of the lighting circuit is uniform, the capacitances to ground will be directly proportional to, and the voltages to ground inversely proportional to, the respective lengths of wire on the two sides of the individual transformer with open secondary.

As an example illustrating the effect of the relative positions of the constant-current regulator, the individual transformer with open-secondary circuit and the exposure section, consider the arrangement shown in

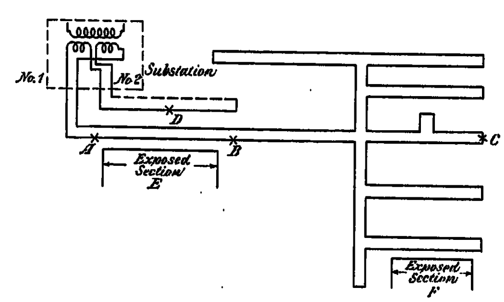

FIG. 5

Fig. 5. This includes a constant-current transformer with double secondary feeding two lighting circuits. It is assumed that the circuits are two-wire throughout their whole length and that the wire arrangements in the two exposed sections are identical.

If a lamp fails at D or at any point along the circuit (No. 2) not involved in the exposure, the harmonic

voltages impressed on circuit No. 1 will be relatively small due to the high impedance of the constant current transformer. The effects in causing noise in either exposure indicated will be correspondingly small. If a lamp fails at A, the wire on one side of the individual transformer with open secondary will be a small fraction of the total length of the circuit, while the other wire will be nearly equal to the total length. The voltages to ground on the wire involved in either exposure and the corresponding noise effects will then be relatively low, the wire having the high voltage to ground not being within the exposures.

If a lamp fails at B, one of the wires involved in the exposure section E will have a relatively large harmonic voltage to ground and the other a relatively low voltage, while both wires in section F will have the relatively low voltage to ground. Thus, considerable noise may be caused in telephone circuits involved in the exposed section E, but relatively little in section F.

C indicates a lamp at the middle of the circuit. In case of lamp failure at C, equal and opposite harmonic voltages to ground will be caused on the two wires. The voltages to ground within exposure E will then be approximately balanced. The voltage between the wires will be equal to the full harmonic voltage caused by the individual transformer. If the circuits in this section are in close proximity, as on a joint line, the noise effects are apt to be as severe as when the lamp failure occurs at the point marked B, especially if the two wires of the lighting circuit are at opposite ends of the crossarm. With the lines separated by the width of the highway, the noise effects will be much less than with an outage at B.

In exposure section F, when the outage occurs at C, the two wires of the lighting circuit will have equal voltages to ground both in magnitude and in phase, and each equal to one-half of the total harmonic voltage generated by the individual transformer. Under these conditions, the noise effects are apt to be severe whether the lighting and telephone circuits are on the same or opposite sides of the highway.

It will be evident from the preceding discussion that it is impracticable to obtain adequate relief from induction merely by symmetrical arrangements of the lighting circuits. While such an arrangement might be effective for one location of the out-lamp, it might be quite ineffective for some other location. More practicable methods involve the use of group series transformers in combination with circuit rearrangements.

Since the harmonic voltage drop along the lighting circuit is small, the harmonic voltage across the terminals of a series transformer supplying a group of individual transformers, and the voltage to ground on the secondary, are small when lamp failures occur at points other than on the secondary of the series transformer. When a failure occurs, opening the secondary circuit of one of the individual transformers in the group supplied by the series transformer, the harmonic voltages to ground along the secondary circuit of the series transformer are distributed as though the series transformer were replaced by the constant-current regulator. Similarly, the distribution of harmonic voltage along the main lighting circuit is as though the series transformer were replaced by the individual transformer having the open secondary circuit. Thus, when a number of groups of individual lamp transformers are supplied by series transformers, lamp failures cause an important effect only on the secondary of the particular series transformer in which the outage occurs and on the main circuit and not on the secondaries of the other group-series transformers. If the telephone exposures involve only the secondary sides of the group series transformers, the number of lamps which may cause noise due to outage will be much less than if all individual transformers were directly in series with the main circuit. Thus, a large reduction in noise interference due to lamp outage may often be obtained by rearrangement of the lighting circuit so that the sections involved in telephone exposures are secondary circuits of series transformers supplying a limited number of individual lamp transformers.

Failure of a lamp on the particular secondary loop involved in the exposure will introduce the harmonic voltages on this section of circuit. If the lighting and telephone circuits are on joint lines, or if there is but a single lighting-circuit wire present at highway or closer separations, the noise effects may be very severe when a lamp fails on the section involved. With two-wire lighting circuits at highway separations having a comparatively small number of lamps the noise effects due to one lamp being out will usually be much less than a similar lamp failure on a circuit having a comparatively large number of lamps. This is due chiefly to the shorter length of the circuit having a limited number of lamps as compared to one of a large number. When a failure occurs on one of these shorter circuits at such a point that the voltage to ground on one side of the individual transformer with open secondary is large, as compared to that on the other, the length having the higher voltage will be so short as not to constitute a very serious exposure. If the failure occurs at a point on the circuit, so that the exposed section is between the series transformer supplying the circuit and the individual transformer with open secondary, the lengths of wire on the two sides of this individual transformer will be nearly equal, and therefore, nearly equal and opposite voltages to ground will be set up on the two wires within the exposed section.

Similar results may be obtained by the use of small pole-type constant-current regulators, controlled by time-clocks or by series relays in another lighting circuit (the so-called cascade arrangement). As compared to the circuit supplying a number of group series transformers, distortion of wave-shape on a main series circuit is avoided. This facilitates coordination in many cases as it is often difficult to avoid exposures

with the main series circuit when the group series transformers are employed. Failure of lamps on the individual circuits will affect only the wave-shape of the circuit upon which they occur.

Effects of out lamps on the individual circuits where supplied by group series transformers or separate regulators may be avoided by replacing the lamps on the circuits involved in the exposures with *straight* series lamps without individual transformers.

It is very difficult to obtain satisfactory conditions from the standpoint of induction from this type of circuit by lamp maintenance alone. A very high degree of maintenance is required, necessitating careful and frequent inspections and prompt replacements of the failed lamps. On circuits containing 100 lamps each, an average outage of only one per cent corresponds to one lamp out on each circuit which as already shown may cause considerable noise in exposed telephone circuits. In some instances, where less careful maintenance routines have been followed, an average outage of between three and four per cent has been noted, resulting in severe noise conditions in exposed telephone circuits.

As an aid to obtaining a very high degree of maintenance, a device known as an "Out Lamp Indicator" has been developed. The device consists of a filter in combination with a milliammeter which is connected to the secondary of a potential transformer, the primary of which is connected across the line terminals. The filter cuts off from the meter substantially all current of fundamental frequency, but permits the transmission of the higher harmonics which are generated by an individual transformer with open secondary circuit. The magnitude of the reading obtained with one lamp out depends upon the rating of the individual transformer and the ratio of the potential transformer. In order to avoid an excessive fundamental frequency voltage on the network and saturation effects on the potential transformer, it is necessary to limit the secondary voltage to approximately 120 volts. Readable deflections with one individual transformer with open secondary circuit may be obtained with potential transformer ratios up to 50 to 1.

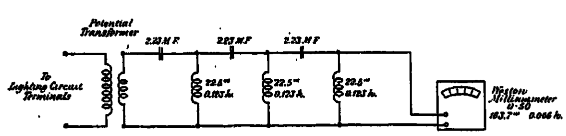

Fig. 6

A diagram of the filter with constants of the elements is given in Fig. 6. Fig. 7 shows a frequency response curve of the combination indicating the milliamperes in the meter per volt at the potential transformer secondary terminals at various frequencies.

In employing this device in maintaining the circuits, readings are taken on the lighting circuits indicating whether or not lamps are out and how many. The circuits may then be patrolled and the out lamps replaced. Experience has indicated that lamps near the end of their life fail immediately after a surge such as when the circuit is deenergized or when energized after having been out of service. If readings are taken

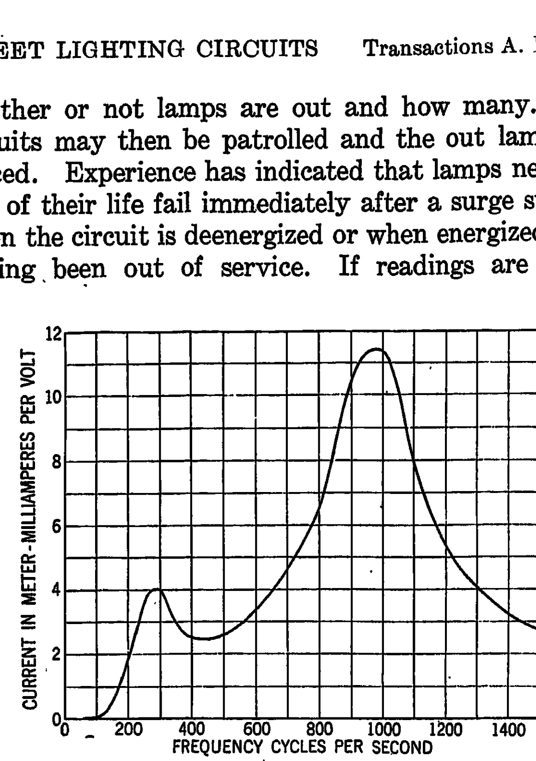

Fig. 7—Frequency Response Curve of out Lamp Indicator Milliamperes in Meter per Volt at Secondary Terminals of Potential Transformer

shortly after the circuits are energized and the out lamps replaced, all lamps are likely to remain in service for the rest of the night. If indications are not obtained on a given circuit, patrolling is, of course, not necessary. Where a circuit is made up partly of straight series lamps with film cutouts and partly of individual-transformer type lamps, no indication will be obtained of an outage of one of the straight series lamps.

Another valuable aid to maintenance is the practise followed by one large company of replacing lamps at definite intervals less than full life in connection with the cleaning schedule. The replaced lamps are then submitted to a photometer test and if not up to standard are destroyed. The lamps indicating additional useful life are then reinstalled in circuits that are not involved in exposures with telephone circuits. This method, in conjunction with the use of the out-lamp indicator, has, except for an occasional outage, eliminated inductive trouble from these circuits.

While great improvement may be effected in many cases by the application of the measures discussed above, the most direct and fundamental remedy for noise interference from this type of circuit would be the provision on each fixture of a device which would short-circuit the individual transformer when the associated lamp fails. However, unless such a device can be secured at a cost which would not sacrifice the economies obtainable by the use of the high-current lamps with the individual transformers, it would become cheaper to place the lamps directly in the series circuit omitting the individual transformer. Due to saturation of the individual transformer, only a small increase in the effective voltage across the secondary takes

place, a much larger increase occurring in the value of the peak voltage. Some device the operation of which depends upon the peak voltage seems most promising and least likely to be subject to false operation due to surges.

Conclusion

Close cooperation between the power and telephone utilities, as in all matters involving the relations between these utilities, is needed to prevent or overcome interference from lighting circuits, particularly in planning extensions or new construction. It is hoped that the information given in this paper will prove useful to power and telephone engineers in their cooperative efforts to solve these difficulties.

Discussion

R. R. Cowles: The present tendency of the Pacific Gas & Electric Company is toward the use of small series street-lighting loops with incandescent lamps only. These series loops are 6.6-ampere and are supplied from a multiple-series constant-current transformer installed on the pole in the same manner as any other distribution transformer. These constant-current transformers are of the moving-coil type, fundamentally similar to those formerly used inside of stations. In size they range from 5 to 20 kw. each, depending upon the average size of the series incandescent lamps which are connected to the circuit. It is the aim to avoid long loops and to restrict the number of lamps per circuit to approximately 60.

These transformers are connected on the primary side to a 4000-volt, four-wire, three-phase, star-connected feeder circuit, said circuit being switched from the substation just as any other 4000-volt commercial feeder. Where the primary neutral is available no additional neutral is extended for the street-lighting feeder. Single-phase lines are run in various directions to supply the territory in the same manner as single-phase lighting feeders are branched from a three-phase feeder for commercial light and power consumers. The effect of the above arrangement is greatly to improve the reliability of street-lighting service through the elimination of long series loops and the resulting reduction in potential on these series loops. Multiple 4000-volt feeders have proven their reliability on the system of the Pacific Gas & Electric Company; hence no new features are involved in this type of feeder circuit. The constant-current street-lighting transformers are furthermore removed from the substations, thereby providing room for other apparatus which cannot conveniently be placed outside of the station.

The 6.6-ampere series street-lighting incandescent lamps are standard for 4000-lumen lamps and less. This is a slight departure from previous practise which indicated the desirability of using series transformers or auto-transformers with lamps larger than 2500 lumens. An improvement in lamp manufacture, however, has made it practicable to use 4000-lumen lamps at 6.6 amperes. Lamps larger than 4000 lumens are operated at 20 amperes, necessitating the use of series transformers or auto-transformers installed on the same pole or in the same fixture which supports the lighting unit. The film cut-outs are used with all 6.6 ampere lamps, operating without auto-transformer or series transformer.

The use of series circuits with currents in excess of 6.6 amperes has been considered by the engineering department of this company but no action has as yet been taken. Small series loops supplied from individual constant-current transformers, with lamps of higher intensity spaced fairly close, would permit of operation at 15 or 20 amperes if the characteristics of these lamps demanded it. Consideration should also be given to methods of switching street-lighting circuits from a remote point which would make possible the use of even smaller loops and considerably simplify the apparatus involved therein. There are a number of types of remote-control apparatus already developed and a number more in process of development. It appears to the writer that the use of radio control for this purpose might be worked out to a practical and economic application at some future time.

C. A. Heinze: Any power engineer who has had relations with the American Bell Telephone Company will notice that the telephone engineers all tell the same story. The main thought in all of their papers is cooperation between the power engineers and the telephone engineers.

I want to state, first, that the electric utilities want to cooperate with the telephone company. We recognize the fact that we have mutual services to render, but I should like to ask Dr. Trueblood just how far the American Bell Telephone Company will go in cooperating with the electric utilities in sharing part of the expense in safeguarding the telephone companies' equipment.

S. B. Hood: Mr. McCurdy recommends some of the usual remedial measures, principally isolating transformers. That is the 100-per cent remedial measure of telephone engineering, and in most cases it is a 100-per cent remedial measure, but in very few cases is it the measure which the power man wishes to adopt. It adds to the investment, adds to the losses in the system, more or less interferes with the regulation, and has a great many objectionable features.

Another recommended cure on series circuits is the straight-series lamp. That is very nice until we get to the higher candle-power. We are all developing "white ways" that require higher densities of lighting. Therefore, recommending the type of lamp which the lamp manufacturers are not prepared to furnish is looking far into the future.

It seems to me that possibly a better recommendation which they could make—particularly since Dr. Trueblood is so enthusiastic over the multiple system—the better cure where inductive exposure is used, would be to change the lamps in that particular exposure to multiple, using a series relay for controlling. Of course, the recommendation for closed loops and balancing the lamp on a loop is very effective, but when you put a series street-lighting system with both wires looped on the same street, as far as the investment goes, it is practically getting back to a multiple system.

It seems to me, however, that in all these papers the indication is that no matter how far apart our past differences of opinion have been, we are all gradually coming closer together; the telephone men and power men are gradually getting down to a uniform system which I think is a very promising outgrowth.

R. G. McCurdy: The tendency of the development towards the use of smaller series street-lighting loops as described by Mr. Cowles in his discussion of the Pacific Gas and Electric Company's practises, from the standpoint of inductive coordination, is in the right direction. Because of the smaller number of lamps per circuit and since the constant-current transformer is closer to the lamp load, the length of any given circuit is much reduced and in case of failure of lamps equipped with individual transformers, the length of circuit upon which the harmonic voltages are impressed, and which may be involved in inductive exposures, is much less than when circuits of a large number of lamps are employed. In many cases also, this method of operation would facilitate supplying separately "white ways," where lamps of high candle-power equipped with individual transformers are used, and outlying sections where in many cases, only straight-series lamps are employed.

Mr. Hood referred in his discussion to the disadvantages of the straight-series lamp, especially in districts where high-density lighting is required. As brought out in my paper, how-

ever, it is very often the case that these high lighting intensities occur in the densely populated sections of cities and towns, where both the telephone and lighting circuits are in cable. In such cases the occurrence of "out" lamps equipped with these transformers is unimportant from the inductive standpoint. In other cases, where the "white-way" section may be of limited extent, it will often be practicable to connect the high-current lamps to circuits not involved in telephone exposures having as far as possible only straight-series lamps on the circuits involved in the inductive exposures.

Many of the difficulties of coordination discussed in the paper are inherent with the series system, and it would doubtless be less difficult to coordinate with multiple systems. The remedy suggested by Mr. Hood, therefore, of changing the lamps in a particular exposure section to multiple, using a series relay for controlling, would probably be an effective one. As far as the incandescent systems are concerned, however, it is felt that the difficulties existing with the series circuit would be overcome by the use of a reliable form of cut-out with lamps equipped with individual transformers or auto-transformers.

Opportunities and Problems in the Electric Distribution System

BY D. K. BLAKE[1]
Associate, A. I. E. E.

Synopsis.—An illustrative electric service system is analyzed to show the importance of the distribution system for the benefit of those not familiar with distribution problems. The diversity factor and load factor are employed to show their effect on investment and losses. The important subject of a-c. secondary networks is discussed relative to switching, induction regulators and a-c. elevator equipments. The circumstances which make single pole switching preferable are outlined. A new, simple and effective connection of the control circuits of induction regulators to ensure stability in parallel operated circuits is described. The present status of a-c. elevator equipments is outlined with emphasis on the merits of Ward-Leonard control where high class service is required.

The new translator network is analyzed at length in order to show its performance and inherent difficulties. It gives a three-phase, four-wire, 115/230-volt system which in no way effects the consumers meters or utilization devices. The author's opinion is that it may be adopted on the grounds of company policy rather than on technical and engineering economic grounds.

Other distribution problems are briefly mentioned. Recent developments in carrier-current control for street lighting equipments are encouraging. Static condensers located at the load center of distribution circuits prove economical in some cases. Various automatic and remote control sectionalizing schemes are under consideration in order to restore service on feeders quickly.

INTRODUCTION

THE purpose of this paper is two-fold: first, to present material to attract the attention and arouse the interest of young electrical engineers in the technically-neglected subject of electric distribution systems; secondly, to discuss several important problems appertaining to a.-c. secondary networks which have become, at the moment, of vital interest to the advanced distribution engineers. It seems to be quite generally admitted that the distribution system is in need of engineering study and of good engineers to do the work. There is nothing spectacular about the conventionalized distribution system and, therefore, little to attract the attention of a young engineer who is looking for a field that is not overcrowded and that will give him an opportunity to do some original and constructive work. There seems to be a general but erroneous opinion that there are not many technical problems involved in distribution. On the contrary, there are plenty of technical and even mathematical problems. But the emphasis herein is not placed on the technical side but on the need of initiative and judgment in the attacks on the problems. What is needed now are engineers who can bring an old distribution system up to date and appropriately plan it for the future growth. This work requires engineers of the same high caliber as those who have accomplished such marvelous results in generating stations, transmission lines, and sub-stations.

RELATION OF THE DISTRIBUTION SYSTEM TO THE ENTIRE SYSTEM

It is the purpose of the following discussion to consider the relation of the distribution system to the entire system. It is not claimed that the divisions and figures given represent accurately any particular system, but it is believed that this method gives a comprehensive picture of a large system and the important position of the distribution system in it.

Large modern electric service systems may be conveniently divided, for the present purpose, into four major divisions: viz., generation, transmission, transformation, and distribution. It is important to observe that this system is virtually a four-link chain and to remember that "a chain is no stronger than its weakest link." In an ordinary chain, each link carries as much load and is, therefore, just as important as each of the other links. Similarly the same load is carried by each major division of the electric service system and, logically, the distribution system is therefore just as important as any of the other divisions.

Service and *economy* must always be kept in mind

1. Central Station Engineering Department, General Electric Company, Schenectady, New York.

Presented at the Pacific Coast Convention of the A. I. E. E., Seattle, Wash., Sept. 15-19, 1925.

by the designer in every part of the system—Service first and economy second. Rarely can these two factors be separated. *Reliability* may reach its peak in generation, transmission and transformation improving the service as a whole, yet the service rendered the consumer is no better than the reliability of the distribution system. Maximum *economy* may be obtained in generation, transmission, and transformation, but there is still a long way to go in the whole system economy if the distribution system is neglected. It is evident from the foregoing review that to render excellent service at maximum economy a well laid out distribution system is necessary.

The distribution system itself may be analyzed in a manner similar to the foregoing main analysis and subdivided into the following parts: the primary feeders

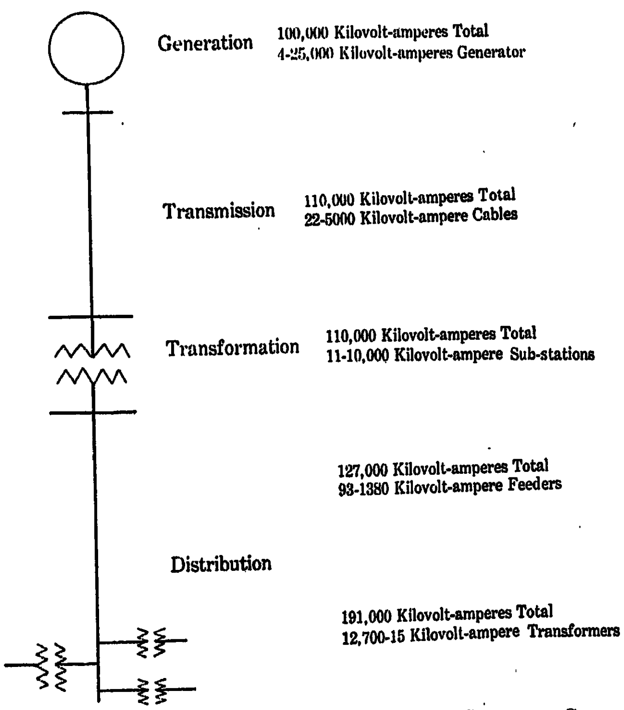

Fig. 1—Major Divisions of Electric Service Systems

and mains; the distribution transformer and related devices; and the secondary mains and service wires. This method of subdivision is made according to the *electrical* functions. Another subdivision may be made according to *physical* characteristics, namely, poles and fixtures, copper wire, and distribution transformers with their related devices such as lightning arresters, fuse cutouts, and temperature indicators.

With these methods of dividing the distribution system in mind, it may be asked how the distribution system differs in character from the rest of the system and also how it compares in the matter of money invested. Suppose it is assumed that Fig. 1 represents a radial system with one main generating station rated at 100,000 kv-a. and that the transmission lines are underground 13,200-volt cables, radiating from the generating station. In an actual system an appreciable amount of power may be supplied to electric railways and sold to other public utilities as well as to large power users. However, for the purpose of illustration, it is assumed that all of the 100,000 kv-a. is supplied to general light and power loads and that there are no inter-connections between substations to form a transmission network as is frequently the case.

The total kv-a. rating of the transmission cables exceeds the total kv-a. rating of the generators because the peak load on most transmission cables does not occur at the same time the peak load on the generating station occurs. When some cables are carrying full load, others will be carrying less than full load. If the peak loads of all the cables are added and divided by the peak load on the station, the well-known diversity factor is obtained. Therefore, the rating of the generating station may be multiplied by an average diversity factor of 1.1 for this radial system, to derive the approximate rating of the transmission cables which is 110,000 kv-a. The usual rating of each cable is about 5000 kv-a. which means that there are 22 cables. There is no diversity between substations and cables in this case because the same power that enters the transmission cables enters the substations. The total substation rating is then 110,000 kv-a. Since 10,000 kv-a. is a good average size substation, there will be 11 of them. It is well to point out here that the relation between generator, transmission cable, and substation ratings will be improved by the use of tie lines between the substations, because the diversity between these parts is changed by the transfer of power through the tie cable. Knowing the substation rating, the distribution feeder ratings can be determined by using an average diversity factor of 1.15 which will give about 127,000 kv-a. in feeder circuits. The usual distribution circuit for such a system will be rated 200 amperes, 1380 kv-a., 2300/4000 volts, three-phase, four-wire. Dividing this into 127,000 kv-a. gives about 93 distribution circuits. Notice how, as depicted in Fig. 1, the system is split up into small kv-a. units which increase in number and total kv-a. rating proceeding from the generating station outward. This is further emphasized when determining the number of units and rating of the distribution transformers. Multiplying the total feeder rating of 127,000 kv-a. by an average diversity factor of 1.5, 191,000 kv-a. is obtained as the total rating of the distribution transformers. This rating is almost double the generator rating to supply them. The average size of distribution transformer may be chosen at 15 kv-a.; therefore, there will be in this illustrative system, about 12,700 transformers. These distribution transformers will not be located in one building as is the equipment in a generating station but the transformers will be mounted on poles and are thereby scattered over a large area. In addition to the transformers there will be mounted with them such related devices as the fuse cut-outs, lightning arresters, and temperature indicators.

A cut-out with each transformer means 12,700 cut-outs, while a lightning arrester with each transformer means 12,700 arresters. Now, if these devices are not applied to the system with care and thought, a great deal of money will be wasted and losses incurred which might be saved. A standardized method of mounting these devices which would save a dollar is multiplied 12,700 times when the whole system is considered. If it were possible to connect all the distribution transformer secondaries together to form a secondary network, then, theoretically, all of the diversity factors back to the generators are removed and the system rating throughout is 100,000 kv-a. Of course, such networks can be formed only in limited areas of high load density.

It is easy to see from the foregoing analysis that the investment in the distribution system must be a large part of the total investment in the system. In some systems, it may be 30 per cent, in others 60 per cent. Distributing companies which purchase energy from

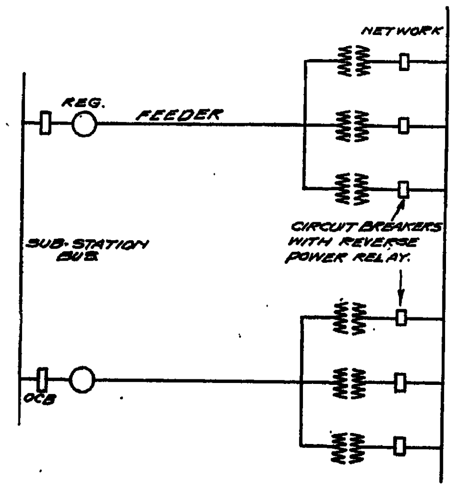

FIG. 2—MULTIPLE FEEDER NETWORK RECEIVING GENERAL FAVOR

large systems have practically all of their investment in the distribution system. These facts clearly indicate that a distribution system which is well laid out will effect large savings in investment and appreciable improvement in service.

The load factor on the distribution transformers may be taken as 20 per cent. There is a relation between load factor and diversity factor such that the load factor of 20 per cent on the distribution transformer may be multiplied by the transformer diversity of 1.5 to obtain 30 per cent which is the load factor of the feeder. Carrying this method all of the way back the load factor for transformation is 34.5 per cent, transmission 34.5 per cent, and generation 38 per cent. Observe that the distribution transformers are used about one-half as much as the generators.

The losses which occur in the distribution system have to be transmitted through the rest of the system and for that reason it is important that losses in the distribution system be reduced to a minimum. A kilowatt loss in the distribution system means more than a kilowatt at the generating station switchboard because some additional loss is incurred in transmitting it. Obviously, the kilowatt lost in the distribution system costs more than a kilowatt lost at the generating station. The distribution transformer has lower losses as well as lower cost per kv-a. for a large size than for a small size; therefore, a well laid out system should have the highest possible average size distribution transformer.

There are many other points which may be added, but it is believed that the foregoing discussion sufficiently emphasizes the importance of and opportunities in the distribution system.

A-C. SECONDARY NETWORKS

General. One of the foremost problems now confronting distribution engineers is the a-c. secondary network for areas of high load density. These are now generally supplied by the well known d-c. Edison three-wire system, which is very expensive. The purpose is to obtain the more economical polyphase a-c. network which will permit supplying lighting and power loads from the same set of mains and which will approach the Edison system in reliability.

Single-Pole versus Three-Pole Subway Switches. Where networks are under consideration the multiple feeder type of network shown in Fig. 2 is meeting with general favor. The circuit breakers in the low-voltage side of the transformers trip on reversals due to short-circuit currents or transformer core loss and are automatically reclosed when voltage conditions on the incoming feeder are correct for carrying load. This type of system is in use at New York City and New Orleans and is described in A. H. Kehoe's article, *Underground A-C. Network Distribution for Central Station Systems*, JOURNAL of the A. I. E. E., June 1924; and W. R. Bullard's article, *Study of Underground Distribution Systems for the City of New Orleans*, JOURNAL of the A. I. E. E., Nov. 1924. All of these systems under consideration, except one, anticipate using Y-connection on low-voltage side of the transformer. If the secondary switches used with this system are too large, it may be necessary to rebuild the opening of many vaults and in quite a few cases new vaults will be necessary because wall space is not available for large triple-pole switches. It is believed that a small, compact single-pole switch has many advantages over a larger triple-pole switch. The following discussion is intended to show the practical advantages of three small single-pole switches over one large triple-pole device.

The single-pole switch may be conveniently arranged for the lead from transformer to enter at the bottom and the lead to the network arranged to leave from either side of the box at the top. The three-pole switch is not readily designed with leads out either side but with leads out through the top which requires an extra bend

in the cable and more head room. The dimensions of the subway box may be made small enough to permit the switch to be lowered through any manhole opening that will admit the transformer it is to be used with. In many vaults a large wall space cannot be found on which to mount a large triple-pole switch but three small spaces may be found to mount three single-pole devices. The single-pole switch may be designed small enough to permit mounting it on the side of the transformer tank where wall space is not available. The box may be supported from the floor by a pipe and braced to the wall by angle irons. The wall surface back of the box may be used for racking cables.

It is frequently necessary to build transformer vaults on side streets or in alleys because other sub-surface structures make it impossible to obtain a space large enough for a vault to contain three transformers. Three small vaults large enough to contain one transformer and one single-pole switch may in many cases be located on the main thoroughfare, thereby avoiding the cost of a duct line from the feeding point to the transformer vault. The three smaller vaults will have the additional advantage of increased wall surface per transformer for heat radiation and this may be sufficient to make special ventilating systems unnecessary. The complete switch with an aluminum subway box may be designed with a weight low enough to permit two men to handle it without the use of tackle. A three-pole switch would be much heavier and more difficult to install. After the box is mounted inspection will be easy because of the small cover. The design could be made so that the panel, on which the circuit breaker and relay are mounted, may be easily removed from the box after removing some small bolts without disturbing the mounting or cables. This feature permits all testing and repairwork to be done at the shop where complete units in working order may be taken to a vault and readily placed in the box after the defective unit is removed. One company anticipates using a single-pole device with four outgoing leads at the bottom. Each lead is connected in the box through a fuse or copper link. This arrangement makes a combined switch and junction box which is economical in cost and space requirements.

The foregoing discourse emphasizes the advantages from an installation standpoint but there are also a few advantages from an operating standpoint. The substation breakers in the primary feeder may be arranged for single-pole switching as is now the practise in radial feeders on some systems. The single-pole switch in the transformer secondary removes only one-third of the transformer capacity when there is a transformer failure or a single-conductor cable failure. The loss of this phase does not cause single-phase operation of induction motors because the three-phase relation is maintained by the other feeders. It is not probable that a failure which may occur on another feeder will be on the same phase and it is, therefore, quite an advantage to keep unaffected phases of a feeder in service since they may be of help when trouble comes on other feeders.

Transformer Load Division. The use of a reactance in series with the transformer is the method being used to improve the division of load between transformers. Some companies are using special transformers with the reactance increased to 10 per cent and others are using external reactors consisting of laminated iron punchings slipped over the lead cable on the low-voltage side of the transformer. This latter method has the advantage of using standard transformers and permits the location of the reactance at points where they are needed. The dimensions of such a reactor to increase the reactance to 10 per cent on a 100-kv-a. transformer with 115 volts secondary isa pproximately 16 in. by 6½ in. by 6½ in. For a 75-kv-a. transformer the length will be

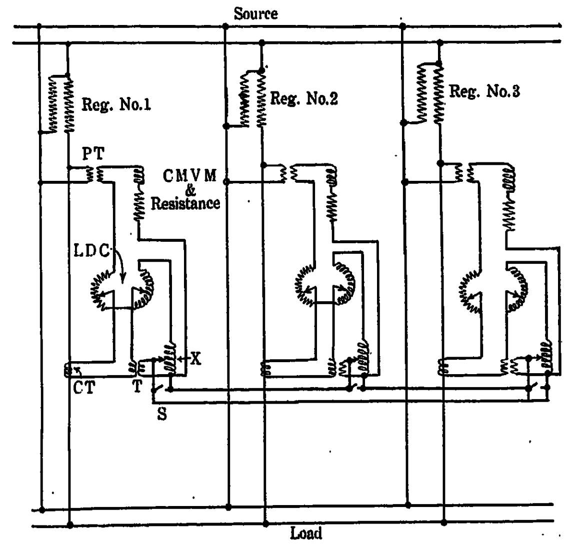

FIG. 3—NEW CONNECTION OF INDUCTION REGULATOR CIRCUITS TO ELIMINATE CIRCULATING CURRENTS

increased to 18 in. on account of there being less current to give the same voltage drop. One reactor is used with each transformer by looping both leads through the punchings to obtain the magnetic effects of both leads.

A New Regulator Connection. When the network is supplied by several high voltage feeders with induction regulators, it is necessary to take some precautions to eliminate circulating currents caused by improper operation of the induction regulators. Several schemes have been proposed but the one shown in Fig. 3[2] seems to be the most promising because of its simplicity and ease of installation. This scheme can be applied to a varying number of regulators, it being possible to connect in additional feeders or disconnect them as may be desired without changing the adjustment of any of the apparatus.

To the conventional regulator connections, there is added in Fig. 3 a transformer T in the current trans-

2. Devised by Mr. F. J. Champlin of Pittsfield, Mass.

former circuit, a reactance X in the potential transformer circuit, and a switch S which serves to short circuit the reactance. This switch S is interlocked with the feeder breaker so that when the feeder switch is opened, the switch S is closed and vice versa.

When conditions are normal the load current circulates through the secondaries of T but none through X. If there is a circulating component in the feeders which flows out through the No. 1 feeder and returns over the other feeders in parallel then two-thirds of this component flows through No. 1 X and one-third through the other two reactances in series but in a direction opposite No. 1 X. By properly arranging the polarities of the current and potential circuits the voltage set up across X will be opposed to the unbalanced potential set up across the line drop compensator by the circulating current. This voltage set up across X will assist the secondary voltage of the potential transformer thus tending to operate the contact making voltmeter so that the regulator will be returned to a stable point, thereby eliminating the circulating current.

No mechanical interconnection or additional current transformers in the feeder are required. The transformer T and variable reactance X may be contained within a single housing, mounted on the switchboard. A certain amount of resistance may be used in combination with the reactance. Three regulators using the exact connections shown in Fig. 3 have been connected in parallel and tests were made including change in voltage, change in load, and change in position of the individual regulators. No matter what change was made, the regulators would always adjust themselves to eliminate the circulating current which is the general source of trouble in the parallel operation of single-phase regulators.

A-C. Elevator Equipments. Practically all companies contemplating networks expect it will not be economical to change all the d-c. motors to a-c. and, therefore, it will be necessary to maintain an appreciable part of the d-c. for many years after the a-c. secondary network is in successful operation. Where 60-cycle power is available[3], a-c. motors can be applied directly to elevator engines and give quite satisfactory operation up to maximum car speeds of 450 ft. per min. A large number of these a-c. equipments are being installed, even in such buildings as hotels, office buildings, and apartment houses, and are giving service which is entirely satisfactory to the owners. Power consumption on these a-c. driven elevators is generally less than with any form of d-c. driven elevator as there are no shunt field or dynamic braking resistor losses.

When a high-grade elevator is required and the power supply is alternating current, Ward-Leonard control with separate motor generator set for each elevator is the ideal. Such equipments are being installed on both geared and gearless equipments in fairly large numbers even for car speeds as low as 250 ft. per min. with geared machines and as high as 700 ft. per min. with gearless machines. For gearless machines the demand is almost entirely for Ward-Leonard control even where d-c. power supply is available, due to smoother and more refined control and to reduced power consumption where the service is heavy and the number of stops per car mile is large. Where the service is light and the stops per car mile is low, the power consumption may be slightly greater.

When all charges against an elevator are considered, such as interest on investment, depreciation, maintenance, operator's salary, rentable area of building occupied by elevators, etc., it is readily seen that power consumption is a relatively small percentage of the total. Such features, then, as reliability, maintenance, smoothness, refinement of control, accuracy of landings, and speed regulation may play a more important part in determining the type of drive to use than power consumption. For example, where it can be shown that the above features will so speed up the service as to permit one less elevator to be used with Ward-Leonard control than would be necessary with rheostatic control,

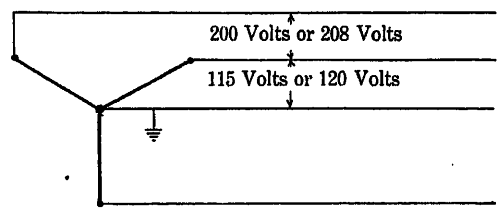

FIG. 4—Y-CONNECTED NETWORK NOW IN USE

the use of Ward-Leonard would be justified on account of the saving effected, even though the operating conditions were such that power consumption on Ward-Leonard might be slightly greater. Such cases have actually arisen.

Rates of acceleration and retardation can be made substantially quicker with Ward-Leonard control than with d-c. rheostatic control without discomfort to the passengers, since they follow a smooth curve instead of being jerky due to cutting out the steps of resistance on a rheostatic control.

It is well recognized that the greatest percentage of elevator outages with rheostatically controlled elevators are due to control troubles and that most of the maintenance expense occurs on the control panel on account of the heavy currents handled and the size of the devices. With the Ward-Leonard system, the control panel contains only small devices handling small field currents. Consequently troubles from burning are negligible and mechanical wear and tear is reduced to a minimum. The motor-generator set, while a rotating piece of equipment, is simple and easily understood by the average electrical maintenance man and its maintenance

3. Discussion on elevators contributed by J. A. Jackson of Schenectady.

consists of an occasional oiling, keeping it clean, and an occasional change of brushes. The reduction in maintenance charges should be a considerable item in favor of Ward-Leonard control.

This type of system will cause practically no voltage fluctuations on the mains since there are no a-c. motors switched on the line every time the car is started. The motor generator set is started without load and should cause no voltage dip.

The New Translator Network. Most companies that do not have two-phase distribution are considering the three-phase, four-wire system and some which have two-phase distribution are giving more consideration to the two-phase, five-wire system.

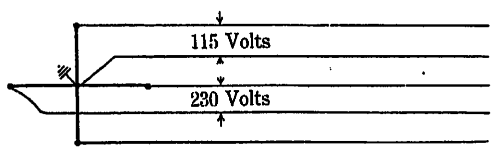

Fig. 5—Proposed Two-Phase, Five-Wire Network

The three-phase, four-wire system shown in Fig. 4 will have either 115 volts for lamps and appliances and 200 volts for motors or 120 volts for lamps and appliances and 208 volts for motors. In the first case standard appliances and fractional horse power motors are suitable while the 200 volt is just on the lower limit for standard 220-volt polyphase motors. Some engineers believe this system will be successful at 115/200

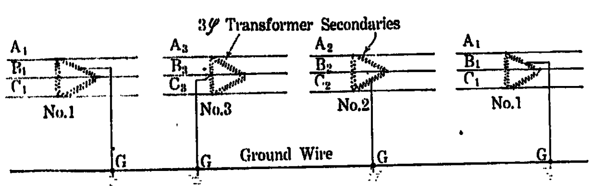

Fig. 6—Delta-Connected Transformers for Supplying Lighting and Power Loads

volts because the majority of motors are not generally applied to devices that require rated starting, pull-in or pull-out torque. Where difficulty is anticipated or encountered they expect to install auto-transformers to step the voltage up to 220 volts. This would require the separation of the motor circuits from the lighting circuits in the building or the use of auto-transformers with each motor. Other engineers believe 200 volts is too low for motors and expect to use the 120/208-volt system. It is believed that the 208-volt is sufficiently above the lower voltage limit (198 volts) of successful motor operation so that with a system regulated for lighting no trouble should be experienced. On the other hand, standard 110-volt appliances and fractional horse power and fan motors are not recommended for operation at 120 volts particularly when it is likely that the voltage will exceed 120 volts occasionally. Lamps and some heating appliances rated at 120 volts are considered as a standard rating while all fractional horse power and fan motors are standard at 110 volts with a permissible variation of plus or minus five per cent. However, some companies are supplying the 110-volt devices on 120-volt radial circuits. With the three-phase, four-wire system it will be necessary to use polyphase metering with the extra testing difficulties

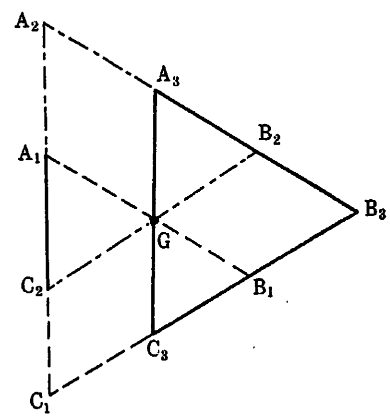

Fig. 7—Vector Diagram of Voltage Relations of Transformers in Fig. 6

or two single-phase meters with the extra bookkeeping when supplying three-wire services since the voltages from each line to ground are not in phase with each other.

The two-phase, five-wire system shown in Fig. 5 gives standard voltages for lamps, appliances and

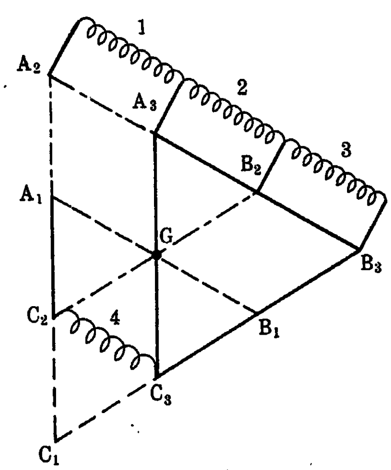

Fig. 8—Vectorial Relation of Combined Transformer and Auto-Transformer Used to Form Tie Between Transformers in Fig. 6

motors. The single-phase, three-wire meter may also be used on three-wire services. The two phases are easier to balance than the three phases of the other system. The two-phase motor, four-pole control equipment and T-connected transformers are objections to this system. Three-phase is ideal for generation and transmission and while two-phase may be ideal for

distribution the combination is undesirable to the manufacturers from the point of view favoring the standardization of three-phase motors and ultimate disappearance of two-phase motors.

It will be observed that either of the foregoing systems affects the consumer's equipment. If it is the Y-connected three-phase system the polyphase motors operate at sub-normal voltage and the fractional h. p. motors and some appliances operate above the permissible voltage limit in case of 120/208-volt system.

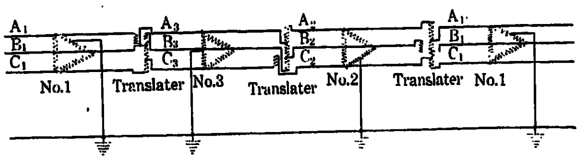

FIG. 9—SAME AS FIG. 6 EXCEPT THAT TRANSLATOR IS ADDED TO PERMIT TRANSFER OF POWER BETWEEN SECTIONS

With the two-phase, five-wire system the consumer may have difficulty in obtaining short shipments on two-phase motors and will have additional investment in control equipment and wiring.

Mr. John C. Parker, of Brooklyn, has devised a three-phase, four-wire network system which gives 115 volts for lamps and appliances and 230 volts for polyphase motors. The lighting load may be balanced on all three phases. This system may be best understood by first referring to Fig. 6. Each bank of transformers

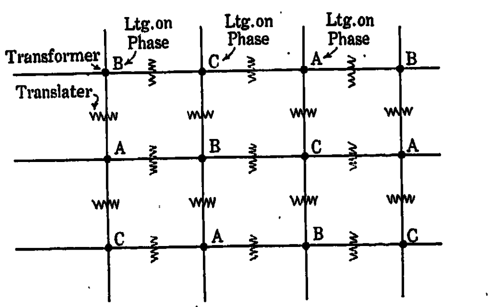

FIG. 10—SECTION OF NETWORK SHOWING MOST ECONOMICAL LOCATION OF TRANSLATORS

supplies a set of three-phase, four-wire mains; but the mains cannot be tied together directly to form a network, since the grounds on the different phases would short circuit the transformers. The grounds are necessary and limited to 150 volts to ground on lighting circuits in order to protect human life. The ground is common to all of the transformers and, therefore, the vector diagram shown in Fig. 7 may be drawn. It will be observed that the voltage difference between A_3 and A_2 (also between B_2 and B_3) is equal to ½ the delta voltage and is in phase with the voltages $A_3 - B_3$ and $A_2 - B_2$. The voltage difference between C_2 and C_3 is equal to $A_2 - A_3$ and in phase with it. An auto-transformer consisting of a coil with taps which divide the coil into three equal parts may be connected to A_2, A_3, B_2 and B_3 as shown in Fig. 8. This auto-transformer is excited from $A_2 - B_2$ at 230 volts and also from $A_3 - B_3$ at 230 volts. Load may be transferred through the auto-transformer with $A_2 - B_2$ as the input circuit and $A_3 - B_3$ as the output circuit or $A_3 - B_3$ may be the input circuit and $A_2 - B_2$ the output circuit. In order to complete the connection between the No. 1 bank and No. 2 bank, it is necessary

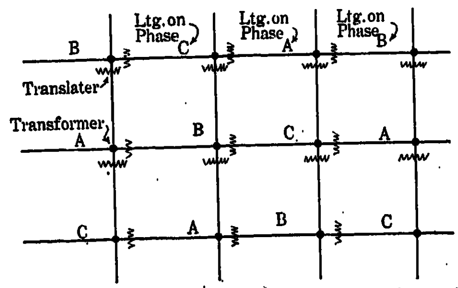

FIG. 11—SECTION OF NETWORK SHOWING MORE PRACTICAL LOCATION OF TRANSLATORS

to make a connection between C_2 and C_3. This is done by a coil which is wound on the same core as the auto-transformer.

With the extra coil added as in Fig. 8 we have a combined transformer and auto-transformer which can be used to transfer single-phase or three-phase power from bank No. 1 to bank No. 2 or from bank No. 2 to bank No. 1. In case of a transfer of three-phase power coils, No. 1, No. 3, and No. 4 carry the current between banks. Under this condition the flux due to the load of the one coil is equal and opposite to the resultant flux due to the load of the other two coils. Therefore, the load current does not magnetize the iron to cause an excessive drop. The device may be designed with a regulation as good or better than the best distribution transformers. Single phase lighting load is carried by coils No. 1 and No. 4 when it is transferred from section No. 2 to No. 3 and coils No. 3 and No. 4 when it is transferred from section No. 3 to No. 2. In this case also the load fluxes are opposed and do not magnetize the iron core. It is, therefore, possible to operate such a network and

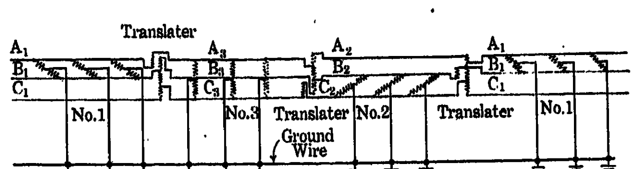

FIG. 12—METHOD OF CONNECTING TRANSFORMERS TO AVOID TRANSMITTING LIGHTING LOAD THROUGH TRANSLATORS

supply lighting load from all three phases. In order to transfer load between sections No. 3 and No. 1 and sections No. 1 and No. 3 a translator (combined transformer and auto-transformer) is connected similar to the one between sections No. 2 and No. 3. Fig. 6 is redrawn in Fig. 9 to show the translators connected.

The most economical application of the translator

occurs when it is located so as to transfer a minimum amount of load. This location is midway between transformers with a uniformly distributed load. Fig. 10 shows the appearance of a network with translator applied in this manner. In this location the translator will have to carry half the load connected to a section of main in the event of a transformer outage. To avoid changing the translator with load growth, it would seem best to design it with one-half the current carrying capacity of the cable. However, it does not seem probable that the translator can be applied in this manner for best economy because the load is not uniformly distributed and it is frequently desirable or necessary to connect transformers to mains at other points than the junction point. It seems best, therefore, to design the translator with a current carrying capacity equal to the current carrying capacity of the cable. It is believed that three standard sizes such as 325 amperes for 4/0 cable, 450 amperes for 350,000 cm. cable, and 600 amperes for 500,000 cm. cable would cover most underground networks. With the cable and translator designed for the same capacity it would be unnecessary to make any changes in translators until it became necessary to change the cable mains. Load growth or transformer locations will have no effect on the translator capacity.

The translator may be located in the same manhole with the transformers as shown in Fig. 11 or may be installed in the middle of the mains as in Fig. 10. The location of the translators fixes the phase areas for the lighting load. The letters *A*, *B*, and *C* in Figs. 10 and 11 refer to the phases which supply the lighting load. After the translators are once installed the phase to which lighting loads are to be connected may be plainly marked in order to avoid confusion when making connections. In case it should be necessary to change the location of a translator it will not be necessary to change the lighting services from one phase to the other, but only to reconnect the cable mains so as to shift all the lighting load affected to the proper phase.

The primaries of the distribution transformers may be either Y- or delta-connected. Transformer $A_3 - B_3$ in Fig. 9 will supply through the translator some of the lighting load connected to $A_1 - B_1$, and transformer $B_3 - C_3$ will supply some of the lighting load connected to $B_2 - C_2$, so that with a Y-connected on the high voltage side, no appreciable transformer capacity will be lost by these units ($A_3 - B_3$ and $B_3 - C_3$) supplying part of the lighting load connected to $A_3 - C_3$.

It is obvious that the transformer connected to $A_3 - C_3$ will supply more of the lighting load connected to $A_3 - C_3$ than either $B_2 - C_2$ or $B_1 - C_1$ because the latter have to supply the lighting load through a longer distance as well as through the translator. It seems that Fig. 9 would be preferable where the power load is more important but where, as is usual, the lighting load is more important, it may be better to use the connections shown in Fig. 12. The lighting load is then supplied direct from the transformers. The motor load is supplied through the translators on two phases and direct from the transformer on the third phase. If there were no lighting load the motor would receive unbalanced voltage because of the extra drop in the phases supplied from the translators; but the lighting load on the third phase will bring these voltages more nearly equal and the result will probably be that the motor will receive no more of an unbalanced voltage than it would on any other system. Even if the full drop through the translators unbalanced the voltages applied to the motors, the unbalanced voltage should not be sufficient to be serious. When the primaries are delta-connected it would seem that this method of connecting the transformers would cause serious unbalanced currents when supplying motor loads because the translators and an appreciable length of mains are inside the delta causing unequal impedances in each side, with the result that the transformers nearest the motor would supply much more current to the motor than the other phases. While this may be true for a particular section, it should not be

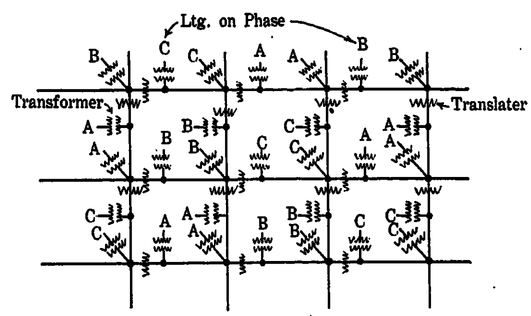

FIG. 13—APPEARANCE OF NETWORK WITH TRANSFORMERS CONNECTED AS IN FIG. 12

true for several sections because the unbalanced current occurs on different phases for adjacent sections and, therefore, the result would be an approximately balanced load. With the primaries Y-connected the division of load between phases is not affected because unequal impedances do not cause an unequal division of load in the Y-delta connection, but an unequal division of magnetizing current. Where the power load is heavy it will be best to add additional units for the other two phases. Fig. 13 shows the appearance of a network with the lighting supplied direct from the transformers. In each manhole there may be three transformers and two translators or they may be placed in different manholes. It is not necessary to have a translator for each main as in Figs. 11 and 12, but the network may be divided into phase areas as shown in Fig. 14. Transformers may be added on the other phases where the power loads are heavy or located far from the other phase areas. The areas, of course, need not be equal geographically but equal electrically.

This system may be used with single-phase switching by connecting the neutral of the Y-connected prim-

ary to the fourth wire and using double-pole switches for each transformer secondary. With single-conductor primary cable it will be possible to operate the system with a minimum capacity removed from service during a cable failure. The remaining transformers on this feeder would operate in open delta with transformers on the remaining feeders.

It is obvious that use of the translator necessitates unbalanced currents in the mains of each section because of the connection of the lighting load to one phase. However, the Y system also has unbalanced load in each section of the mains. While it is possible to balance the lighting load on a Y-connected system so that the feeders supplying the network are well balanced, it is not possible to have each section of secondary mains so well balanced. The translator system, of course, will be appreciably more unbalanced in each section than the Y-connected system; but the translator system also may be operated with the feeders supplying the network as well balanced as the other. In the Y-connected system the loads are balanced over the three-phases by individual loads; but in the translator system the loads may be balanced over the three-phases in groups, which should be much easier. Assume that in the Y-connected system the lighting load is balanced over the three phases and that the current in each phase is 100 amperes for lighting at unity power factor and 100 amperes for power at 86.6 per cent power factor. The resultant current is 194 amperes for each phase. Then with the translator system when the lighting load is supplied from phases *A-B* the current is 237 amperes for *A* phase, 207 for *B*, and 87 amperes for *C* phases. The power factor of 86.6 per cent for the power load was chosen because this gave the condition of maximum current carried by one phase. When the power load is one-half the lighting load the current in each phase of the balanced Y-connected system is 145 amperes; but with the translater system the current in *A* phase is 194 amperes, *B* phase 181 amperes, and *C* phase 44 amperes. When the power load is one-quarter the lighting load the current in each phase of the balanced Y-connected system is 122 amperes; but with the translator system the current in *A* phase is 172 amperes; *B* phase, 162 amperes; and *C* phase, 22 amperes. The effect of this on the losses in the mains is to decrease the total loss 5.5 per cent below the Y-connected system in the first case and increase the losses 14 per cent and 26 per cent in the second and third cases. These values refer to the case where no lighting load is transmitted through the translator under normal conditions. Where some lighting load is carried on the other 2 phases through the translators, phases *A* and *B* would carry relatively less current and phase *C* relatively greater current, so that the resulting unbalanced current would not be so bad as previously indicated. Furthermore, the power loads in many cases will be almost equal to the lighting load which is not a bad condition. The annual charges of the energy losses in the secondary mains is about 12 per cent to 17 per cent of the total losses in substations, feeders, transformers, and mains. Therefore, whatever change occurs in the secondary main losses, when using the translator system, will not have an appreciable effect on the total losses.

In the system shown in Figs. 9, 10, 11 and 12 the effect of the cost of the translaters when designed to

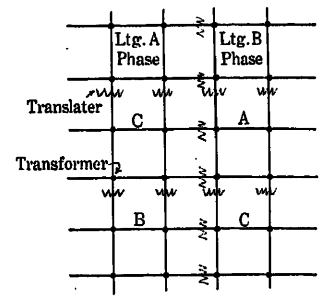

FIG. 14—LOCATION OF TRANSLATERS TO FORM LARGER PHASE AREAS FOR LIGHTING LOAD

carry full cable capacity on the total investment from substations to secondary mains depends on the relation of the current carrying capacity of the secondary mains to the transformer capacity. A system with 500,000 cm. cable has a much higher percentage increase investment when three 100-kv-a. units are used than when three 200-kv-a. units are used. A study of some systems indicates extremess of 7 per cent to 15 per cent

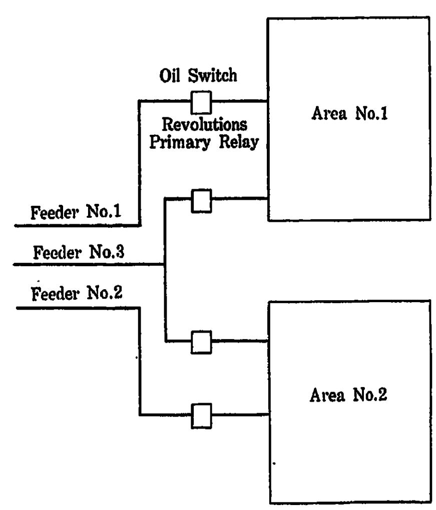

FIG. 15—PROPOSED TYPE OF PRIMARY DISTRIBUTION NETWORK

increase for systems having 13,200-volt primaries and 5 per cent to 12 per cent increase for systems having 2300/4000-volt Y primaries. Where the translators are used to define phase areas as in Fig. 14 instead of one in each section of secondary mains the increase in investment then, of course, depends on the number of areas for each phase. When the losses are added, the increase in annual charges ranges from 6 per cent to 20 per cent. The lower figure applies to a case where the vaults are large enough to receive the translators without any changes or new vaults.

It is apparent from the foregoing analysis of the translator system that there are technical and practical difficulties as well as increased cost and losses of the translator system over the Y-connected and two-phase systems. All of these difficulties and extra costs are borne by the electric service companies and none by the consumer. The consumer is not called upon to operate his single-phase devices at excessive voltage or his polyphase motors at sub-normal voltages, to increase his investment in control equipment, nor to contend with possible delays in shipment of two-phase motors. Three-wire lighting services may be metered with the standard 3-wire meter instead of two single-phase meters or one polyphase meter. It seems, therefore, that the selection of the translator system must be upon the grounds that the electric service company does not want to run any risk of inconvenience to, or complaint from, the consumer nor to cause the consumer any extra cost but prefers to accept the extra cost and complications. The Y-connected or two-phase network represents about one-third the annual cost of an Edison system, and, therefore, it does not seem that the extra cost of the translator system would be an unreasonable burden to assume. This extra cost, of course, is borne by the industry but the cost would be less than the cost to the industry to properly take care of off-standard equipment used on Y-connected and two-phase networks.

Notes on Other Important Problems

Street Lighting Control. The methods now in use to control either pole-type, constant-current transformers or multiple lamps are time clocks, pilot-wire circuits, and cascade systems. The latter may include time clocks and pilot wires or may consist only of a succession of lighting circuits connected through suitable switching equipment. In some cases pole-type, constant-current transformers are supplied and controlled by a special 2300-volt feeder which covers the substation territory.

In addition to the foregoing control schemes, there is the possibility of carrier current control which at present seems very promising. The ordinary primary feeder conductors may be used to conduct the carrier wave to the receiving equipments which may control either a pole-type, constant current transformer or a multiple lamp circuit. The development of a successful carrier-current system low enough in cost may be the deciding factor in the extensive use of multiple street lighting circuits supplied from the usual distribution transformer.

Power Factor Improvement. One large eastern company has installed a few pole-type static condensers at the load center of their distribution circuits. This practise may prove a very economical practise in a number of cases by postponing, for a few years, the building of a new circuit in a growing territory. After the new circuit is built and some of the load transferred from the old to the new circuit, the condensers may be removed to another circuit.

It may also be shown that it is more economical to improve the power factor of some systems at the distribution feeder load center with special pole-type static condensers than to improve it at the substation. Twelve circuits were studied assuming the pole-type condenser cost $5.00 kv-a. more than substation corrective equipment. The extra annual charge was found to be 67 per cent of the saving in $I^2 R$ loss from the substation to the load center. The location of standard condenser equipments by the electric service company on the consumer's premises would be somewhat more economical, since larger standard outfits may be used at a lower cost per kv-a.

Feeder Service Restoration and Maintenance. Considerable study is being given to a number of schemes to restore service on feeders quickly. The extensive use of automatic reclosing feeder equipments has accomplished considerable in quickly restoring service. The records of one large eastern company show that for a period of over a year, 58 per cent of the operations tripped once, reclosed once and stayed in. On the second reclosure 11 per cent stayed in. These circuit trippings resulted in practically no interruption to service. This case indicates that there must be a remainder of around 30 per cent in actual interruption to service on feeder circuits to be restored quickly by other means. Various automatic and remote control sectionalizing schemes are under consideration.

One large middle-western company proposes to try out a form of primary network shown in Fig. 15. The advantage gained by the use of this scheme over simple radial operation of feeders is the automatic preservation of service in case of a short circuit on a feeder cable. In case of a short circuit on a primary ring or its branches the service in that area is interrupted the same as it would be with radial feed. Under normal operation advantage is gained in using the reserve feeder to carry load, in improved regulation, and reduction in losses.

Discussion

C. E. Carey: I wish to discuss one or two details in Mr. Blake's paper. He mentions primarily the single-pole protective unit. He goes into detail and attempts to establish the justification of the multiplicity of parts. However, the question of single-phase or single-pole units cannot be separated from the whole network. Personally, I believe that the multiple unit is the real solution. We have seen that there are certain state laws requiring that we open the entire circuit, rather than allow an unbalance on the networks and produce inductive interference. It is much better, I believe, to clear the entire trouble as quickly as possible rather than take out one phase at a time. The three-pole unit will not occupy as much space in the manhole as three single-pole units. The automatic a-c. network protector is a device which does everything you can expect it to do. It is designed to go into the standard 35-in. manhole cover. The covers of the units are of aluminum, are light, and can be handled by one man. Furthermore, if inspection

of these devices is to be made the time consumed will be less with three-pole units than with three single-pole units.

In regard to the translator, I believe that anything we put in to complicate the network is defeating the purpose of the a-c. system. The whole thing resolves itself back into continuity of service, simplicity, and low cost, and the only way we can arrive at that service with a reasonable cost is to trim it down to just the bare necessities.

Practically everyone will agree that if we had it to do over again, we would never put in a d-c. network. We have it, but what are we going to do with it? If we attempt to change to an a-c. network we are confronted with the cost of changing over the customer's equipment, which will be so high in some cases that the interest and other fixed charges on that additional cost will more than carry the high losses in the d-c. network. However, one solution is being used to bring the economics of the d-c. very close to those of the a-c. network, the use of the automatic substation. The automatic substation gives primarily the same type of distribution as the a-c. system, that is, high voltages to the converting stations and low voltage for distribution. The automatic substation is reliable and economical. A real analysis of the problem will often show that it is better to hold to the d-c. network, remove the concentrated manually operated stations, and distribute that conversion power over a network to a large number of small conversion stations, approaching extremely close to the transformers on the a-c. network in losses and other factors which come into the distribution problem.

Henry Richter: In considering a-c. secondary networks, it is well to recognize that the network systems mentioned by the United Electric Light and Power Co. as used in New York City—and also those in New Orleans—use triple-pole automatic network units exclusively, and that similar systems and network units will shortly be in operation in Dallas, Memphis, Knoxville, and Atlanta. Minneapolis will install these units as the load grows, preparatory to forming a network. These comprise all the companies that have completed or started to construct a network like that of Fig. 2, using automatic network units.

In practically none of the installations in these cities, where space might permit single-pole units to be installed, has it been necessary to add to the dimensions of new manholes in order to accommodate the triple-pole network unit; or to construct new manholes, or enlarge old ones, due to any extra space required because single-pole units were not available; or even to take up space in an existing vault that could be ill spared. These networks are considered justifiable only in heavily loaded areas where the loads are too great to be supplied in the single-phase manner. Three-phase transformer banks are, therefore the rule, ranging in size from three 25-kv-a. single-phase transformers up to three 100-kv-a. transformers. The manholes and building vaults to accommodate such banks, to allow for growth of load, to ensure no excessive temperatures, and to permit proper racking and maintenance of cables, must be of such size that there is no lack of wall space for a triple-pole network unit. It is customary to locate this unit on the wall opposite that along which the three transformers are placed, and close to a corner of the manhole. In existing manholes having three-phase banks formerly part of a radial primary and secondary system, the triple-pole network units can usually be put into the space formerly occupied by the large secondary junction boxes. In most cases, this space is not otherwise useful, for the network systems employing these automatic network units are so simple that nothing else is necessary in the manhole besides the transformers with or without small reactors, the cables and the network unit. Further, it is an erroneous idea that single-pole network units, particularly in a submersible housing, can be made so tiny that they can be installed in any odd corners of a manhole. The desirability of giving them proper maintenance makes such procedure far from advisable even if they were so small.

If it is desired to have the leads to the secondary mains leave the triple-pole network unit horizontally, to either side, it is extremely simple to provide a small terminal box where the outgoing leads emerge from the top of the submersible housing. This small box can have wiping nipples mounted horizontally at either side. The extra bend in the cable is thus eliminated. However, in none of the cities enumerated has this been necessary. Seven and a half feet is an average height for these transformer manholes as determined by good subway construction practise and even with a triple-pole network unit for a bank of three 100-kv-a. transformers there is no cramping of cables entering and leaving the housing.

When the triple-pole network unit was being designed, it was recognized that the submersible housing must pass through a certain minimum-size manhole opening. A country-wide survey was made and it was learned that the great majority of companies have adopted 35-in. diameter round as the smallest opening for transformer manholes in existing or contemplated construction. Apparently this minimum was governed by the dimensions of 100-kv-a., single-phase subway transformers. Accordingly the triple-pole units of all sizes were designed to pass through a 35-in. diameter round opening. In none of the six network cities mentioned (and together they are typical of all other cities) will it be necessary to rebuild the opening of any manhole to permit the unit to pass through; and careful investigation shows that in none of the cities where three-phase networks are being considered for the future will there be any difficulty in this regard.

If it becomes necessary to rack cables along the wall back of the network unit, it is just as easy to mount the triple-pole unit on a pipe framework braced to the wall as for the single-pole unit, since the two types are not very different in depth. However, just as with junction boxes, subway oil-circuit breakers and such apparatus, electric service companies do not consider this good practise in manholes. In only one case has a company mounted on a transformer tank a piece of auxiliary apparatus of such size as a single-pole network unit might be, and there the conditions are unlike those anywhere else in the country. In general, the place for such equipment is against a wall.

Where subsurface conditions make it impossible to build a manhole for three transformers at any particular location in the street on a main thoroughfare, three solutions have been found to be applicable: (1) obtain a vault in the basement of a building; (2) install a manhole under the sidewalk, or (3) locate the manhole in the street as close to the desired location as possible. In almost no case has it been impossible to use one of these methods. Where the third method must be employed, the distance from the most desirable location is usually so short that the cost of the extra length of duct line is small compared with the extra cost of three smaller manholes over one larger one. It is also doubtful whether city authorities will permit subsurface obstruction at three neighboring points.

The triple-pole network unit for manholes is constructed with a window of heavy, wired glass, amply strong, in the cover; this makes inspection of the principal parts easier than by taking off the cover of a single-pole unit. If it is necessary to get at the parts inside, the time to remove the few extra bolts or lugs holding the cover on the triple-pole unit is negligible. The aluminum cover of the triple pole unit can be handled by one man without difficulty.

The design of the single-pole unit to permit easy removal of the panel from the housing when it is desired to make repairs at the shop follows the identical idea that is incorporated in the triple-pole network unit design. Similarly, right from the start, fuses have been installed on the panel of the triple-pole unit, in series with the outgoing leads, to make a separate

fuse box unnecessary. These last two points, therefore, do not apply exclusively to single-pole units.

The paper claims that the single-pole unit conforms with the method of single-pole switching inherited from the radial system of distribution. In a properly designed three-phase network system single-pole switching is no longer necessary and may be abandoned. In a radial system it is better to have some light than no light, when trouble occurs on a feeder, and hence the value of single-pole switching. Networks are designed so that in no case will trouble on any feeder cause interruption of any service fed from the secondary network. Among such troubles there must always be included the putting out of service of all three conductors of a feeder, either by phase-to-phase short circuit in a three-conductor cable, or, where three single-conductor primary cables are in the same duct, by the melting down of all the conductors by a severe fault to ground on one of them. It may even be necessary to provide for the possibility of a manhole fire taking two feeders out of service simultaneously. Thus, there is no necessity in complicating the system to get the insurance that goes with keeping two of the phases in service when the third goes out. One large company even plans to use three-phase regulators on three-phase feeders serving an important network, and some are thinking of using triple-pole oil-circuit breakers at the station and three-phase distribution transformers where these can be passed through the existing manhole openings.

The paper overemphasizes the importance of manhole installations. While the difficult conditions encountered in manholes must be met and are being met, it should be remembered that of a total of over 600 triple-pole network units that will be in operation by the end of this year, less than one third will be in manholes.

Three single-pole units have three operating mechanisms in place of one for the triple-pole unit, and this means more parts to maintain. Three units together have more surface to gasket than a triple-pole unit, which gives more chance for water to leak in with any given type of construction. Three units also occupy a greater total space in the manhole, and every cubic foot is valuable. When the design of automatic network units was first under consideration, all these factors were weighed and the single-pole type was abandoned as inferior to the triple-pole type.

The simplest method of ensuring stable operation of regulators on feeders operating in parallel on a network[1] does not require any extra apparatus such as the transformers T and reactors X of Fig. 3. It employs only a transfer switch, corresponding to switch S for each feeder. This scheme was given a thorough test on the network system of the United Electric Light and Power Company, where it originated, and was shown to be entirely satisfactory.

One of the greatest problems in connection with secondary networks is the type of combined light and power secondary system to employ. Mr. Parker has blazed the trail in an effort to devise some scheme whereby the advantages of the combined system may be obtained and the disadvantages of the star connection avoided. It cannot be too strongly urged that others follow in his steps. However, it must be pointed out that the translator scheme may introduce disadvantages that outweigh those of the simple four-wire, star system, and these disadvantages may so handicap the development of the network idea as to result in a loss to all concerned.

In the star system of Fig. 4 the only voltage unbalance at the motor terminals is caused by unbalance of load in the secondary mains due to varying sizes of the loads as encountered along the street. This unbalance may be reduced to a negligible amount by care in connecting two-wire and three-wire services on alternate phases. From the analysis of the translator scheme it is evident that it may easily result in voltage unbalances of at least 10 per cent at the motor terminals. For the same per cent voltage unbalance on a motor as per cent voltage reduction, both the heating and starting torque are affected to a worse degree in the case of the unbalance. Hence the effect on motors would be worse with the translator scheme than by operating them at 199 volts on a 115/199-volt star-connected secondary.

Adding extra transformers on other phases to obtain a better balance of voltage where power loads are frequent not only increases the number of transformers on the system, but also calls for larger or more manholes to house them. This would materially cut down the savings in transformer capacity gained by the diversity that networking makes possible.

Where the 115/199-volt star-connected secondary system is employed it has been necessary to use auto-transformers on not more than 15 to 20 per cent of the motors connected to the system in order to supply satisfactory voltage. On the basis of power load equal to half the lighting load these auto-transformers represent less than 7 per cent of the capacity of the secondary system. If the translators, equivalent in capacity to the total capacity of the secondary system, cause an increase of investment averaging 10 per cent of the entire distribution system cost, the auto-transformers necessary to ensure satisfactory operation of motors on a star system involve an increase in investment of less than 0.7 per cent.

The unbalance of current for the case of power load half the lighting load requires that the wire carrying the maximum current in the translator system use about 60 per cent more copper than for the star system. It would be highly inadvisable to proportion the size of the three-phase wires in the translator scheme according to the loads in those wires, because the sizes would have to be changed from block to block all over the system, and this would complicate the system even more than by adding the translators. Hence all secondary wires would be as heavy as the largest one, and this might mean a 60 per cent increase in the total amount of secondary copper required. Where 500,000-cir. mil copper is taken as the largest size, the extra copper would in many cases require a second main and duct. To these extra costs must be added those of the translators, value of manhole space they would occupy, and losses in secondaries and translators. Even the seven-wire, separate-light-and-power secondary system would not cost more and would be simpler. The increase in cost due to all these items might easily overcome any saving gained by combining power and light mains and defeat the very purpose of the translator scheme.

If the electric service companies want to inconvenience the fewest number of customers using a star-connected system, they will adopt the 115/199-volt three-phase system, as only the polyphase motor users will be affected. In the few cases where tests show insufficient voltage, the simple auto-transformers can be employed to boost the voltage. In Memphis, a 115/199-volt system of this kind has been in operation for over ten years and the customers are entirely satisfied. In Rochester, for several years, light and power loads in large buildings downtown have been supplied by 120/208-volt transformer banks in the basements and, even though motors up to 40 h. p. are connected at the end of long risers and no auto-transformers are employed, the customers praise the service.

It must be recognized that for most systems an a.-c. network system, even though fed at 13,200 volts, is just a little less than half the annual cost of a d-c. system and hardly less than 80 per cent of the cost of an a-c. radial system. These ratios have been checked independently by the engineers of five large systems. Hence, we would be deceiving ourselves as to the economic value of the translator scheme for it introduces such elements of additional cost as would wipe out the balance now in favor of a-c. networks.

The control of multiple street lamps or pole-mounting, constant-current transformers supplying series street lamps, by

1. Described in the *Electric Journal*, July, 1925.

means of carrier current over the primary feeders, will represent a great step ahead. One company has tried out such a system, but the operation has been faulty and the relay units on the poles are of such nature as to be relatively expensive. The sender at the substation is also complicated. Another company has developed a simpler form of relay unit, and tests of a number of these, equivalent to at least a full year's service, have proved them satisfactory. This relay unit is compact, substantial and inexpensive. The sender unit is also simple and strongly built.

M. T. Crawford: Mr. Blake's paper refers to a method shown in Fig. 5 of which the title is "New Connection of Induction Regulator Circuits to Eliminate Circulating Currents." I think I am correct in stating this connection has been used recently by our company in our new Union Street substation and has proved very successful in regulating 4500-volt feeders in a multiple-feed network. One practical point in connection with it has been that some means has been found desirable to automatically disconnect the regulator control circuit on low voltage, so that regulators will not assume, during system trouble, different positions after fluctuations. I mean by that if a short circuit comes on the transmission network, and the voltage of the system as a whole oscillates back and forth, perhaps reaching very low values for brief moments, there is a tendency for the regulators to attempt to follow these voltage variations up and down. By the time matters have settled down again, some of the regulators are in one position and some in another, due to their slightly different characteristics. That has resulted at times in tripping out of network switches on the underground distribution system due to reverse flow of power for brief periods from one feeder into another where the voltage conditions were slightly different. By the simple expedient of providing a low-voltage release on the regulator control circuit, this trouble has been eliminated. The operator at the substation can reset the control circuit after the system has quieted down to normal.

The translator referred to is a very clever development. The Puget Sound Power and Light Company's underground distribution system employs single-phase, three-wire mains for lighting and alternate blocks with longitudinal alleys are placed on alternate phases, so the first alley is on one phase, the second alley on another, and so on. By that method the phases are relatively well balanced at the substation. In places, we have recently installed a fourth wire paralleling the single-phase, three-phase mains to provide small polyphase service. The result has been three-phase, four-wire mains in each alley similar to the ones referred to by Mr. Blake, and the respective alleys in the same phase relation as those shown in his diagram.

The translator, therefore, in our case offers something to look forward to as a possibility of permitting interconnection of the three sets of secondary mains for purposes of phase balancing or load protection if it should be found desirable. However, the addition of apparatus is always to be very closely scrutinized, and its necessity must be proven before it is added, as the simpler a system is, the better the service will always be.

A. H. Kehoe (communicated after adjournment): Regarding Mr. Blake's discussion of single-pole versus three-pole a-c. subway network switches I consider the proper switch to use is the one which will give minimum cost over an extended period. The cost of revising a few existing locations will be negligible on the total installation cost. Tripping and closing elements in these switches represent a major item of cost and single-pole units will nearly triple this cost for each installation. Space, that is, cubical contents, naturally will be less in a three-pole unit than in three single units. These conditions seem to make the three-pole unit the one to be adopted generally. However, I do not favor certain of the existing three-pole switches of the so-called "battleship" construction. If the principal installation advantages set up by Mr. Blake for single-pole switches are used are specifications for three-pole switches, none of the latter's many advantages need be considered except the greatly reduced cost.

Under operating advantages there are several references to separating the phases either in the physical location or for operation of the transformers. I believe this is a case of confusing what *can* be done with what *is likely* to be done. It is possible to separate phases in three transformer vaults but it is probable that one vault three times as long will be cheaper and better if polyphase load is to be supplied. The system of polyphase secondary distribution is primarily for better universal utilization of electric service, as methods of balancing are now successful without it. However, that balanced polyphase loads are desirable at all points on a system, is a design axiom. All progress up to this time points to polyphase rather than single-phase distribution transformers for ultimate use. If the standard three-wire, single-phase system is taken as analogous to the polyphase system, it is evident that two single-phase, two-wire transformers could be placed in separate transformer vaults supplying a three-wire system. This is not likely to be found, however, in standard practise as all the capacity is found in one unit and a vault is built to take this larger unit, as this design gives minimum cost. I believe similar conditions will hold as the polyphase system develops.

Concerning the operating situation with radial distribution, the single-pole substation switches had economical advantages which could be charged to reliability. Since, in network distribution, there must be, and is always, sufficient reserve on each phase to allow for a failure of that phase, in each locality where it exists it is certain that the remaining phases will have sufficient reserve capacity to be eliminated in case of fault. Such operation does not have any effect upon service which can be equated against the increased cost, when the money, if necessary, could be expended to obtain an increased reserve upon all phases so that the particular phase in trouble would benefit by having a greater reserve. I doubt whether single-pole network switches are proper even with those systems already operating with three single-pole switches on four-wire, 4000-volt service, as new load will cause a higher voltage supply to be used than 4000 volts. It is possible to superimpose the new load on to the existing system and avoid the double transformation which is otherwise required.

Mr. Blake describes a method of cross-current compensation as the "most promising." It is, however, neither simpler nor easier of installation than others now in use. The several such connections should be given consideration before applying a definite arrangement to a particular system. The method described makes constant current and power factor the major considerations, while constant service voltage becomes a secondary one. Constant and correct service voltage is one of the most important elements in the business. While the network insures reliability and better voltage regulation than on radial systems this latter should not be compromised unnecessarily. It seems to me to be preferable to design the system for proper balance of load and have the regulating equipment give proper voltage under all conditions. The connection proposed does the opposite. Applying such a connection to a number of long feeders on an extended network makes other connections preferable due to the voltage variation under the ordinary load shifting.

It should be noted that a distribution network does not simulate a bus in respect to voltage or to concentration of load as indicated in Fig. 3 of the paper.

I fail to find in the translator description any reference to the use of this connection on certain distribution transformer secondaries to join and supply the different mains. If such a device ever has a practical application I believe it will be necessary to make it up in such a form, rather than as an auto-transformer, owing to cost and losses involved. Mr. Blake's statement that each section of secondary mains on a Y-connected system is not likely to be well balanced is not in accord with the

purpose of adopting polyphase distribution. In some existing installations a certain amount of unbalance may exist due to the utilization having been designed for three-wire, single-phase service, but new installations are easily balanced and it is only in districts where growth of loads occur that any considerable amount of three-phase, four-wire mains are likely to be installed.

D. K. Blake: Mr. Carey questions the application of the single-pole switch. Mr. Richter's discussion also differed as to the application of the single-pole switch. It is recognized that the objection to the multiplicity of units for maintenance is valid. It is also recognized that a number of large companies will be able to utilize building and sidewalk space and, therefore, for these places the triple-pole switch is preferable. In the synopsis of the paper is this statement: "The circumstances which make single-pole switching preferable are outlined." It was my impression that there was a similar statement in the text, but on reading it over I notice there is not, and, therefore, some wrong conclusions might be drawn because of this omission. In his discussion Mr. Richter seemed to deny that these circumstances exist at all. He mentioned the cities where the large switches are being used. I agree with him that the triple-pole switch is preferable in these cities with one exception. Mr. Richter's references to the design of the switches indicates he misunderstood the paper. No exclusive features are claimed. To include all of these features in a triple-pole switch presents serious difficulties which are expensive to overcome. The operating advantages of single-pole switching may be questionable. Some engineers believe it desirable.

Mr. Richter mentions that the transfer switch shown in the *Electric Journal*, July 1925, corresponds to switch S shown in Fig. 3 of my paper. Switch S is a single-pole auxiliary switch whereas the transfer switch consists of four auxiliary switches or else one auxiliary switch to control an electrically operated double-pole double-throw switch. The cross-connected scheme is not as simple in its operation. All regulators are not adjusted at the same time according to the amount of circulating current passing through them but adjustment is obtained in a sequence. Mr. Kehoe's statement that the proposed connection does not "give proper voltage under all conditions" is not clear to the author. The line-drop compensator in each feeder maintains constant voltage at the load center with varying load. The impedances of the feeders may be different; some feeders may be long and some short. The proposed connection, by substituting a phase shifter at T, can also be used with three-phase regulators which is not true of other connections now in use.

I want to thank Mr. Crawford for telling us of his experience with the new regulator connection. We shall have to learn something about the operation of this connection on the systems where we use the sensitive reverse-power relay. I am glad to learn that Mr. Crawford has found a simple way of correcting the trouble.

It is not evident to the author why the translator system "may easily result in voltage unbalances of at least 10 per cent at the motor terminals." The translator system is simply the tying together of four-wire combined light-and-power mains which are supplied by delta-connected transformers. The unbalance on these mains is due to the lighting load on one phase and since this is limited to 3 per cent regulation that is also the extent of the unbalance on a 230-volt circuit. Heavy power loads are usually supplied with individual transformer banks and, therefore, it is not evident why larger or more manholes are necessary for this purpose on the translator system.

The translator system may be used with single-conductor cable with two of the phase wires larger than the third—just

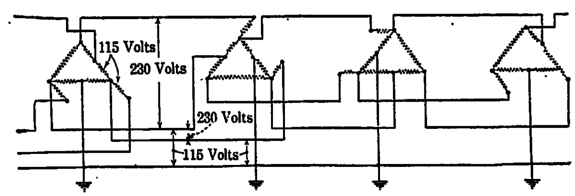

Fig. 1

as is done in radial practise. These sizes would not have to be changed from block to block but would be uniform over the system. The case of power load equaling half the lighting load required that the wire carrying the maximum current in the translator system use about 34 per cent more copper than for the star system instead of 60 per cent as given by Mr. Richter.

Mr. Kehoe refers to a scheme using transformer secondaries. Such a connection is shown in Fig. 1, herewith, utilizing four standard distribution transformers. The main objection to this system is that it is tied up with the primary feeder making it necessary to provide two triple-pole network switches for protection. The translator is independent of the primary voltage. The fourth transformer is greater in kv-a. rating than the translator and very much more expensive in case of 13,200-volt or 11,000-volt primaries. The fourth transformer should be located in the same manhole with the other three while the translator may be located where convenient. Part of the lighting load is supplied from open-delta connections.

Report of the Board of Directors

FOR THE FISCAL YEAR ENDING APRIL 30, 1925

The Board of Directors of the American Institute of Electrical Engineers presents herewith to the membership its Forty-first Annual Report, for the fiscal year ending April 30, 1925. A general balance sheet showing the condition of the Institute's finances on April 30, 1925, together with other detailed financial statements, is included herein. The following is a brief summary of the principal activities of the Institute during the year; more detailed information has been published from month to month in the Institute JOURNAL.

Directors' Meetings.—The Board of Directors held nine meetings during the year; seven were held in New York and one each in Chicago, Ill., and St. Louis, Mo.

Information regarding the more important activities of the Institute which have been under consideration of the Board of Directors, the committees, and the various officers, is published each month in the section of the JOURNAL devoted to "Institute Activities."

President's Visits.—During his term of office, President Osgood has presided at the principal conventions of the Institute in Pasadena, New York City, and St. Louis. In addition he has visited, and addressed, the members of numerous Sections and other engineering groups throughout the country, his itinerary having included Vancouver, Seattle, Spokane, Portland, San Francisco, Panama, Havana, New York, Boston, Lynn, Pittsfield, Troy, Rome, Syracuse, Schenectady, Philadelphia, Washington, Atlanta, St. Louis, Milwaukee, and Madison. He has also addressed meetings of engineering students at California Institute of Technology, Leland Stanford Jr. University, Massachusetts Institute of Technology, University of Pennsylvania, Rensselaer Polytechnic Institute, Syracuse University, and the University of Wisconsin.

Other meetings that President Osgood is scheduled to attend in May and June are: Regional Meeting, Swampscott, May 7-9; Cleveland Section, May 21; Utah Section and Utah Engineering Council, Salt Lake City, May 25; Society for the Promotion of Engineering Education, Schenectady, June 16; Annual Convention, Saratoga Springs, N. Y., June 22-26.

Meetings.—The policy of holding in addition to the Annual business meeting four general meetings of the Institute each year was continued. The meetings held were as follows: Annual, Pacific Coast, Midwinter, and Spring Conventions.

Annual Meeting.—The Annual Business Meeting was held at Institute headquarters, New York, on May 16, 1924. The Annual Report of the Board of Directors for the fiscal year ending April 30, 1924, was presented. The Tellers Committee made its report upon the election of officers for the administrative year beginning August 1, 1924.

Following the business meeting President Harris J. Ryan gave a lecture on "The Atmosphere as a Factor in Electrical Engineering." This part of the meeting was held under the auspices of the New York Section.

Annual Convention.—The Fortieth Annual Convention was held at Edgewater Beach, Chicago, Ill., June 23 to June 27, 1924. Seven technical sessions were held including parallel sessions on three mornings. Thirty-two papers were presented. One session was devoted to standardization including reports by subcommittees of the Standards Committee. The entertainment provided included sightseeing and inspection trips, golf, tennis, dancing, cards, etc. The attendance was about 1000. The annual conferences of the Sections Committee were held on Monday, occupying the entire day and evening; forty-two Sections were represented. A report of the conference was published in pamphlet form.

Pacific Coast Convention.—The Thirteenth Pacific Coast Convention was held at Pasadena, Cal., October 13th to 17th, 1924. Eight technical sessions were held at which twenty-six papers were presented. The total attendance at the convention was 363.

Midwinter Convention.—The Thirteenth Midwinter Convention was held in New York, N. Y., February 9 to 12th, 1925. Twenty-five technical papers were presented at six sessions. Among events of particular interest were the ceremonies in connection with the presentation of the Edison Medal to John White Howell, the Smoker, and the numerous inspection trips. Registration reached approximately 1500.

Spring Convention.—The Fourth Spring Convention was held in St. Louis, Mo., April 13th to 17th, 1925. Seven technical sessions were held and twenty-six papers were presented. The attendance was 700.

Regional Meetings.—During the year two meetings of a new type were held. These were the Conventions or Regional meetings of District No. 1 and District No. 2 held respectively at Worcester, Mass., June 5th and 6th, 1924, and Washington, D. C., January 23rd and 24th, 1925. These Regional meetings were planned and carried out by the Sections located in the respective Districts through suitable District Committees organized in each case under the guidance of the Vice-president of the district. The Meetings and Papers Committee cooperated in obtaining many of the technical papers presented. These Regional Meetings are likely to increase in accordance

with the policy of decentralization formulated by the Officers of the Institute and of the various Districts and Sections.

Abstracts of the reports of the chairman of many of the Institute committees and delegations are included herein under various headings.

Meetings and Papers Committee.—The Meetings and Papers Committee during the past year has concerned itself with carrying to completion work so well started by the last committee including formulation of policies and procedure. The Committee has seriously studied the possibilities of regional conventions at the request of the Board and has formulated a policy with respect to the preparation of papers and programs for these meetings. This policy in brief recognizes the regional meetings as accepted Institute practise, places responsibility for the initiation of the meetings and the papers on the regional organizations, outlines a scheme of regional committee organization for cooperating successfully with the national committee organization, and endorses the principle that regional and sectional papers are eligible to the same treatment as papers presented at national conventions. As worked out with respect to the regional meetings in Districts No. 1 and No. 2 this year this policy has produced good results and the regional meeting promises to be a permanent feature of Institute activities in certain districts.

The national conventions of the year were outlined and the programs were prepared with the idea of reducing the number and improving the quality of papers, securing diversity in topics treated, and obtaining good discussions. The first meeting of the year in Pasadena was unusually successful as it had a large and well diversified program and an attendance of members from all parts of the country. The cooperation of the local committee on the Coast enabled the Meetings and Papers Committee to help greatly in making the convention successful.

The Midwinter Convention in New York was notable for the high-grade papers presented, the good discussions, and the absence of parallel sessions.

The Spring Meeting in St. Louis embodied a well diversified program dealing very largely with application aspects of electrical engineering. A notable feature of this meeting was the papers and discussions on modern power stations.

In the light of developments during the year it would seem that the present arrangement and number of conventions of the Institute meet the needs of the members, provide an adequate outlet for the technical paper production, and meet the budget requirements as to expenditures. A judicious culling of papers and scheduling of papers at more than one meeting solves the publication problem and gives better discussion, and the development of regional meetings permits of a selection and a scheduling of papers with greater flexibility than has hitherto existed. The cooperation of the Meetings and Papers Committee with Sections and Geographical Districts has been continued and developed.

It seems that the Institute organization and plans for the cooperation necessary to obtain good papers and programs at all Institute meetings are perfected and only constructive work along present lines is required to maintain the present degree of excellence in this aspect of Institute activity.

Publication Committee.—The principal task of the Publication Committee is that of managing the publication of the JOURNAL, the TRANSACTIONS, and periodical indexes.

The views of the Institute's officers and members relative to publication policies have been developed through a series of more or less related committee actions.

The Committee on Development, of 1919, in its Report presented various constructive suggestions which have enabled us in the main to meet the wishes of the majority of the members. Broad consideration was given to publication problems by the Editing Committee of 1919, and by a committee of the Section Delegates at the Swampscott Convention of 1923.

Regulations adopted by the Publication Committee, approved by the Executive Committee, were published in the October, 1923, JOURNAL. With practically negligible complaint the policies announced at that time have been continued.

It is difficult to print an equal number of pages of reading matter in each monthly issue of the JOURNAL, but the endeavor has been to limit the amount to about eighty pages of technical material, and twenty pages of all other material, including "Institute and Related Activities." Appropriation of funds for publication of the JOURNAL is made on this basis.

In September, 1924, it became necessary to take advantage of the authority to abstract the longer papers, without invalidating the rule that every paper presented at a meeting shall have full publication in pamphlet form, in the JOURNAL, or in the TRANSACTIONS.

It was so managed that all of the papers presented at meetings during the year 1924 were printed either in full or in abstract in the JOURNAL by the close of the year 1924, so that the January 1925 and following issues of the JOURNAL were available for the printing of papers presented at the Midwinter Convention, 1925, and at subsequent meetings.

The dates of publication of discussion have been advanced considerably, thus bringing the dates of publication of papers and discussions closer together.

All papers presented at Regional meetings of the Institute are considered for publication on the same basis as papers presented at National meetings.

Rapid progress is being made in preparing for early

publication an Index to the TRANSACTIONS covering the years 1911-1921, inclusive. The determination of the end of the period covered was made in view of the fact that the Index should conform in book size with that of the TRANSACTIONS of that period. The size of the TRANSACTIONS page was changed to uniformity with the JOURNAL page beginning with January, 1922.

The Publication Committee welcomes communications from the membership bearing on publication matters and the character of the JOURNAL. All such communications receive careful attention at meetings of the committee.

Sections and Branches.—The great increase in Institute membership during the last few years and the wide distribution of that membership has necessitated the development of plans providing for participation in A. I. E. E. activities of that large portion of the membership who, because of their location, cannot conveniently attend the national meetings. The Regional Meetings which have been held at Worcester, Mass., Washington, D. C., and Swampscott, Mass., (the latter having been held May 7-9, 1925) are indicative of this development. The more thorough organization and the activity of District Executive Committees and a closer affiliation of all Sections with the national Meetings and Papers Committee, are still other steps in that direction. Each year these problems on Section developments are thoroughly discussed at the Sections Committee Conference during the Annual Convention. During the year two new Sections have been authorized, Nebraska and the Niagara Frontier.

A similar development of Student Branches has also occurred with plans under way for a more effective supervision and direction of their work. New Branches were authorized at New York University, South Dakota State School of Mines, and Missouri School of Mines and Metallurgy.

	For Fiscal Year Ending

Standards Committee.—During the past year, the Standards Committee has made great progress in the revision of the Institute's standards. Five sections of the revised standards have been adopted by the Board of Directors and the work on numerous other sections has been carried so far along that it is expected before the end of the Institute year the revision will be substantially complete as regards sections dealing with types of apparatus or branches of the art which are covered in detail in the 1922 Standards of the Institute. With the issuance of these sections a large amount of work will remain in the completion of additional sections covering standards for other types of apparatus or branches of the art; these are now in course of preparation, or are contemplated in the general scheme of the revision of the Institute Standards.

The Standards relating to each type of apparatus are condensed into a small pamphlet making it immensely easier to determine beyond doubt what are the standards applying to that type of apparatus, a determination which, with the growth of the Institute Standards in their old form to a sizable volume, had become a task, in spite of an excellent index.

Furthermore, the subdivision of the Standards has an essential effect on the case with which they can be revised, it being now possible to make revisions in the Standards dealing with each class of apparatus, without involving changes in a large book.

Perhaps the most important effect of the revision, however, is the extent to which it facilitates cooperation with other organizations interested in electrical standardization. There is no other single organization actively interested in all of the Institute Standards as the Institute alone covers broadly the field of electrical industry. However, with regard to almost any individual section of the revised Standards, there are one or more organizations doing standardizing work in an allied field or so closely identified with that field, as to form desirable co-partners with the Institute in the formulation of standards. The revised Standards contain a large amount of new material of value and there are included standards for types of apparatus covered slightly or not at all in the earlier work. Outstanding examples of this are the standards for insulator tests, the standards for electrical measuring instruments, and the standards for arc and resistance welding apparatus.

During the year the Standards Committee has continued its work in coordinating the numerous standardizing activities of the Institute. The Institute is sponsor for nine projects organized under the rules of the American Engineering Standards Committee and has representation on twenty-three additional committees. The Standards Committee works also in very close cooperation with the U. S. National Committee of the I. E. C., and has done a large amount of work preparing information for the guidance of the delegates at the Hague Meeting in April of this year. Attention has been given by the Standards Committee to the closest possible coordination between its work and that of the technical committees so that the Standards Committee might take advantage of all suggestions which the technical committees could make as to desirable fields and scope of new standards in accordance with the recommendations of the Committee on the Review of the Technical Activities of the Institute.

The present organization of the Standards Committee was set up by the Board of Directors in 1922 in view of the increase in complexity of the standardization work in which the Institute is directly concerned, in order to to bring about a complete coordination of the Institute's standardizing activities. This is carried out by having on the Standards Committee representatives of all the different standardizing committees or commissions in which the Institute is cooperating. These organizations are now 58 in number and include in their membership a total of over 900 men, not excluding as duplicates men who are on more than one committee. In order to enable this large committee to function efficiently, the administrative work is carried on by a small executive committee. It is believed that this organization is admirably suited to the requirements of the present situation and has resulted in excellent progress in the Institute's standardizing work.

American Engineering Standards Committee.—The American Engineering Standards Committee which was organized in October 1918 by the A. I. E. E. and four other societies serves as a national clearing house for engineering and industrial standardization, and provides an information service on engineering and industrial standardization matters. The ultimate responsibility for and control of the work rests with the organizations whose representatives constitute the Committee.

The American Engineering Standards Committee is primarily for the purpose of insuring adequate procedure in the formulation of standards and establishing rules that must be observed by the cooperating bodies in order that the approval of the Committee may be given.

Thirty-two national trade, technical, scientific, and regulating organizations are now cooperating bodies; a total of 160 projects in different fields have official status, 19 of these having been approved as American Standard, and 41, as Tentative American Standard. The Institute is sponsor or joint sponsor for nine projects as follows: Safety Code for Elevators, lightning protection, rating of electrical machinery, wires and cables, symbols for the electrical equipment of buildings, electrical properties of aluminum, electrical installations on shipboard, scientific and engineering abbreviations and symbols, and radio. The Institute is also participating in 18 others by representation on Sectional Committees of other sponsors. The Institute is also participating in the revision of two important electrical codes, the National Electrical Code and the National Electric Safety Code. Agreement has been reached to undertake the unification of overhead line material, including certain classes of insulation, and the unification of specifications for poles, bare and insulated copper conductors, in which work participation by the A. I. E. E. will also be given.

In carrying out the work of the Committee an information service has been established. A complete file of American and foreign standards is being gradually compiled and is available to the Institute and its Standards Committee. Close cooperation is maintained with foreign organizations which is of value to the A. I. E. E. in lines not covered by the I. E. C.

U. S. National Committee of I. E. C.—The past year has been a very active one for the U. S. National Committee, inasmuch as a meeting of the Advisory Committees of the I. E. C. was held in London, July 15th to 18th, 1924. The U. S. National Committee was represented at this meeting by the following delegates: C. L. Collens, E. C. Crittenden, L. L. Elden, H. M. Hobart, A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp, C. E. Skinner.

A considerable amount of very important work was transacted at this meeting. An extensive report on this has been prepared and is available at A. I. E. E. headquarters.

It was arranged at the London meeting of the Committee on Action, held subsequent to the meetings of the Advisory Committees, that the next meeting of the Advisory Committees should be held in The Hague, April 16th to 23rd, 1925.

Preparation for this meeting and for representation by a suitable delegation has involved a large amount of work on the part of the U. S. National Committee. The Standards Committee of the A. I. E. E. has been particularly helpful in preparing matter for submission to the U. S. National Committee.

U. S. National Committee International Commission on Illumination.—The past year has been an important one for the U. S. National Committee, I. C. I., inasmuch as a plenary session of the Commission was held in Geneva, Switzerland, July 22nd to 25th, 1924. The meeting was attended by a number of prominent A. I. E. E. delegates.

The work of this Commission is divided into two parts. One consists of papers and the other in the adoption of standards. It is gratifying to note that at Geneva the Commission adopted a number of the proposals laid before it by the U. S. National Committee and that this Committee was represented also by some very able and interesting papers. The meeting was reported in the October 1924 JOURNAL of the Institute.

One gratifying conclusion which the Commission reached was to hold its next plenary meeting in the United States in 1927. In the meantime the work of the National Committee is being directed toward the development of a representative and creditable program for this first American meeting of the Commission.

Committee on Safety Codes.—The Committee on Safety Codes of the American Institute of Electrical Engineers is made up of representatives of the Institute assigned to cooperate with various standardizing committees in matters relating to National Safety Codes.

The chief work of the committee during the past year has been in connection with the revisions of the National Electrical Code. The Institute has been represented on the Electrical Committee of the National Fire Protection Association and has assisted in the revision of the Code through its representation on that Committee and on its various technical sub-committees.

The Institute will be represented by regularly appointed delegates at the annual meeting of the National Fire Protection Association, to be held in Chicago in May, at which time the recommended changes in the Code will be considered for adoption.

American Committee on Electrolysis.—The American Committee on Electrolysis has been practically inactive during the past year, pending the decision by the various organizations represented on the Committee regarding the continuance of the work.

The expectation outlined in April 1924, to the effect that these organizations would financially support the work of the Committee, has not been realized, although a majority of such organizations are in favor of such support. As a result the work of the main Committee has been inactive, although the work of the Research Sub-Committee has gone forward as well as it could without such financial support.

Technical Committees.—Reports on Technical Committees embracing an outline of the year's work and a summary of progress in the industry will be presented at the Annual Convention and printed in the JOURNAL.

Membership.—The results of the Membership Committee's efforts this year are shown in the following table:

	Honorary Member	Fellow	Member	Associate	Total
Membership, April 30, 1924	6	594	2,359	13,496	16,455
Additions:					
Transferred		11	64		
New Members Qualified		1	80	1,901	
Reinstated		3	7	61	
Deductions:					
Died	2	7	13	62	
Resigned		3	23	316	
Transferred			10	65	
Dropped		2	28	734	
Membership, April 30, 1925	4	597	2,436	14,281	17,318
Net increase in Membership during the year					863

Deaths.—The following deaths have occurred during the year:

Honorary Members: C. E. L. Brown, Oliver Heaviside.

Fellows: Henry M. Byllesby, Henry J. Crowley, John L. Harper, James A. Lighthipe, Charles B. McLeer, Charles O. Poole, Hubert S. Wynkoop.

Members: Lawrence Birks, Fred A. Bryan, Earnest L. Buttler, Patrick B. Delany, Henry C. Egerton, Frederick A. Hall, Walter E. Harrington, Arthur Jacob, Nathaniel S. Keith, Benjamin G. Lamme, T. Commerford Martin, Harry F. Randolph, F. J. T. Stewart.

Associates: Chester T. Allcutt, August Andrew, John R. Bainton, Charles H. Baker, Charles L. Baker, Ferdinand N. Bechoff, Ernest F. Bliss, William W. Bradfield, Harry Bruns, William T. Burns, Gordon Cameron, James G. Cockran, James A. Crawford, Edward H. De Witt, John M. Elwell, James B. Foote, Eugene Frank, John M. Frase, William H. Funk, Thomas A. Furlong, Edward R. Gorman, George H. Groenke, Joseph M. Harrison, Lafayette B. Hedge, William E. Holcombe, Theodore R. Johansen, Henry H. Lyon, James E. Macauley, Elmer K. McDowell, George S. McLaren, Samuel H. McLeary, Henry F. Mitchell, Nicholas G. Morrell, Geoffrey C. Nicholson, Thomas W. O'Reilly, Charles H. Parker, Frederick W. Pastor, Claiborne Pirtle, Herbert S. Potter, Clarence Renshaw, Ralph C. Rodgers, Edgar Russell, A. Gero Schmidt, Max Schmidt, Henry K. Sellers, Oscar D. Smalley, Earle H. Shive, Charles S. Sperry, Stanley S. Stevens, Charles R. Sturdevant, Walter D. Sultan, Howard W. Thomas, Robert W. Thompson, Stephen N. Tillman, Claire P. Upson, Foster Veitenheimer, Theodore Vladinoroff, Mabel Weil, Leslie W. Wilcox, John E. Wilson, Santaro Yamato, James B. Yeakle.

Board of Examiners.—The Board of Examiners during the year held ten meetings, averaging about three hours. It considered and referred to the Board of Directors a total of 3912 applications for admission or transfer to the higher grades.

APPLICATIONS FOR ADMISSION

Recommended for grade of Associate	2006	
Not recommended	14	2020
Recommended for grade of Member	75	
Not recommended for admission to this grade	29	104
Recommended for grade of Fellow	1

PROPOSALS FOR TRANSFER

Informally Recommended	17	17
Total number of applications considered		3912

Proposed Constitutional Amendments.—In the spring of 1924 the Board of Directors appointed a committee to consider a revision of the election procedure of the Institute. This committee formulated and recommended a new plan, which was referred to a Committee on Revision of the Constitution.

The latter committee considered the above plan relating to election procedure and also numerous other suggestions from various sources relating to the constitution, and finally made recommendations to the Board of Directors at a meeting in January 1925, embodying proposed amendments which in accordance with the action of the Board were sent to the membership with a letter ballot, under date of February 25, 1925.

The proposed amendments relate to the following subjects: qualifications for membership; admission, transfer, and expulsion of members; dues; life membership; election, terms, and changes in titles, of officers.

The result of the voting upon these proposed constitutional amendments is not known at this writing, but it will be reported at the Annual Meeting of the Institute on the evening of May 15, 1925.

Scholarships.—The governing bodies of Columbia University have placed at the disposal of the Institute two scholarships in electrical engineering in addition to the one previously granted. In consequence, the Institute is now authorized to award a scholarship each year so that there may be one man in each class holding a scholarship on the nomination of the Institute; these scholarships will continue until further notice. Each scholarship pays $350 toward the annual tuition, and reappointment for completion of course is conditioned upon the maintenance of good standing.

The second award was made to Mr. T. Horiuchi of the University of Colorado, who holds a scholarship for the academic year 1924-1925.

Institute Prizes.—At the meeting of the Board of Directors of the Institute of April 16, 1921, recommendations were approved establishing two Institute prizes to be awarded yearly to authors of worthy papers. Each prize consists of $100 in cash with suitable certificate.

The Transmission Prize for 1923 was awarded to J. L. R. Hayden and Charles P. Steinmetz for their paper entitled "High Voltage Insulation." Honorable mention was given to Howard S. Phelps and E. D. Tanger for their paper entitled "A New Method for Routine Testing of Alternating-Current High-Voltage Paper Insulated Cables" and to F. S. Dellenbaugh, Jr., for his paper "Artificial Transmission Lines with Distributed Constants." No eligible paper was entered in competition for the First Paper Prize.

On September 26, 1924 the Directors approved the establishment of yearly "First Paper" and "Best Paper" prizes of $25.00 in each of the ten geographical districts.

Edison Medal.—The Edison Medal for 1924 was awarded to John White Howell, Harrison, N. J., "for his contributions toward the development of the incandescent lamp." The presentation ceremonies took place Wednesday evening, February 11, 1925, at the Midwinter Convention, New York, N. Y.

John Fritz Medal.—The John Fritz Medal Board of Award, which is composed of representatives of the national societies of Civil, Mining, Mechanical, and Electrical Engineers, awarded the 21st medal to John Frank Stevens of New York for great achievements as a civil engineer, particularly in planning and organizing for the construction of the Panama Canal; as a builder of railroads, and as administrator of the Chinese Eastern Railway." The medal was presented at New York, at a meeting held on the evening of March 23, 1925.

Lamme Gold Medal.—A bequest of $6000 was made by the late B. G. Lamme to cover the annual award by the Institute of a gold medal to a member who has shown meritorious achievement in the development of electrical apparatus. Details are to be arranged.

Kelvin Medal Award.—On December 14, 1923 the Committee of Award of the Kelvin Medal Trust named Dr. Elihu Thomson of Swampscott, Mass., as the recipient of the second triennial award. The Trust Fund represents the surplus obtained in connection with a call for subscriptions to erect a memorial window to Lord Kelvin in Westminister Abbey. The award is made by a committee composed of the Presidents of the principal representative British Engineering Institutions, as a mark of distinction to a person who has achieved eminence as an engineer or investigator in the kind of work applicable to the advancement of engineering with which Lord Kelvin was especially identified. The presentation of the medal took place at the Kelvin Centenary Celebration, London, England, on the afternoon of Thursday, July 10, 1924. After the presentation by Sir Charles L. Morgan and response by Dr. Thomson, the Kelvin oration was delivered by Sir Joseph J. Thomson.

Commission of Washington Award.—The Washington Award for 1924 was voted to Arthur Newell Talbot, Professor of Municipal and Sanitary Engineering, University of Illinois, and the presentation was made at the annual meeting of the Western Society of Engineers, held June 9, 1924. This award was made "for his life work as a student and teacher, investigator and writer, and for his enduring contribution to the science of engineering."

Jonas Waldo Smith has been named as the recipient of the 1925 award.

The award is made annually by a committee composed of nine representatives of the Western Society of Engineers and two each from the A. S. C. E., the A. I. M. E., the A. S. M. E. and the A. I. E. E. The award of the medal was established in 1917 by Past President J. W. Alvord of the Western Society "to be

annually presented to an engineer whose work in some special instance, or whose service in general, has been noteworthy for its merit in promoting the public good." The endowment has been increased $2000 by its founder.

Employment Service.—The employment service which the Institute has maintained for many years is now conducted as a cooperative bureau in conjunction with a similar service maintained by the National Societies of Civil, Mining and Mechanical engineers under the title "Engineering Societies Employment Service." It is supported by the joint contributions of the societies and their individual members who are benefited.

As in the past the Service consists principally in acting as a medium for bringing together the employer and the employee. In addition to continuing the publication of the "Employment Service Bulletin" in the monthly Journals and the weekly subscription bulletin, the Secretaries of the four societies in their capacity as members of the supervising board are arranging for the establishment of branch offices of the service in other cities. It is hoped to continue this development from year to year as conditions warrant.

American Engineering Council.—This organization of which the Institute is one of the constituent societies has had an active year in the service of the engineering profession. The Annual Meeting of the Council was held in Washington, D. C., in January 1925, and the Administrative Board held three meetings during the year. Council was active in connection with the passage of the Clarke McNary Act providing a comprehensive forestry policy; it sponsored the Temple Bill calling for the completion of the topographical map of the United States; assisted in securing additional space, personnel and equipment for the Patent Office; appeared at hearings for providing increased salaries for Federal judges, hearings on the Muscle Shoals project, and in connection with government reorganization and centralization of engineering functions in one division. Among other actions taken were:—authorization of a committee to study the Reclamation Report and make recommendations; appointment of a committee on Aeronautics; authorization for publication of manuscript on "Industrial Coal, Purchase, Delivery and Storage." An active part was also taken in many other national and international conferences and the staff furnished a large amount of direct service to member societies including obtaining of speakers, making appointments with government officials, and recommending qualified engineers for important public and private work.

The representatives of the Institute upon the Assembly and Administrative Board of the Council have continued to take an active part in the work.

World Power Conference.—The first World Power Conference was held in London, June 30 to July 12, 1924. It was held at the British Empire Exhibition, Wembly, London, and was promoted by the Council of the British Electrical and Allied Manufacturer's Association, in cooperation with Technical and Scientific Institutions in Great Britain and other countries. A large delegation of members of the A. I. E. E. and other American engineering societies was in attendance.

The Conference was called for the purpose of discussing the technical and economic problems of power development, transmission and utilization, and for promoting general interest in power development. The question of how the industrial and scientific sources of power may be adjusted nationally and internationally was also considered.

A condensed classification of the topics discussed indicates the wide scope of the Conference: Power Resources, Power Production, Power Transmission and Distribution, Utilization of Power, and General—including Economics, Financial and Legal Considerations, Research, Standardization, Education, Health and Publicity. Forty papers were presented by American authors. Numerous receptions, luncheons, banquets, and other social features were arranged by the various National Committees and other organizations. The complete Proceedings will soon be available in book form.

United Engineering Society.—This Society performs for the national societies of Civil, Mining, Mechanical and Electrical Engineers certain specific acts which are governed by contracts, the primary function of the United Society being to hold in trust and to administer for these societies the Engineering Societies Building, in which the headquarters of the national societies are located.

Extracts from the annual financial report of the United Engineering Society were published in the March 1925 JOURNAL.

Engineering Societies Library.—The library of the Institute is combined with the libraries of the national societies of Civil, Mining and Mechanical Engineers, administered as the "Engineering Societies Library" under the direction of the Library Board of the United Engineering Society; this board is composed of representatives of each of the four societies referred to above.

In order to place the facilities of the library at the disposal of persons residing at a distance from New York, a Library Service Bureau has been established, and a staff of expert searchers and translators is employed to cover almost any engineering topic, in the following manner: abstracting, translating, bibliographing, statistical searches and reports, searches for patent purposes, copying, preparing reference cards, etc. A lending department is also maintained.

A copy of the annual report of the Engineering Societies Library covering the calender year 1924 may be obtained by applying to Institute headquarters.

Engineering Foundation.—Engineering Founda-

tion is a trust fund established in 1914 by Ambrose Swasey, of Cleveland, Ohio, by gifts to United Engineering Society as a nucleus of a large endowment "for the furtherance of research in science and in engineering, or for the advancement in any other manner of the profession of engineering and the good of mankind." It is administered by the Engineering Foundation Board upon which the Institute and other national engineering societies are represented. The Board is a Department of United Engineering Society.

The Foundation has made appropriations for various research projects and has cooperated in others.

The annual report of the Foundation is available in printed form.

Representatives.—The Institute has continued its representation upon various national committees and other local and national bodies with which it has been affiliated in past years, and has accepted sponsorship and appointed representatives upon a number of new Sectional Committees of American Engineering Standards Committee. A complete list of representatives is published frequently in the JOURNAL.

Finance Committee.—During the year the committee has held monthly meetings, has passed upon the expenditures of the Institute for various purposes, and otherwise performed the duties prescribed for it in the Constitution and By-laws.

Haskins and Sells, certified public accountants, have audited the books, and their report is appended.

Respectfully submitted for the Board of Directors,

F. L. HUTCHINSON, *Secretary.*

American Institute of Electrical Engineers,
33 West 39th Street,
New York.

Dear Sirs:

Pursuant to engagement, we have audited your books and accounts for the year ended April 30, 1925, and submit herewith our certificate and the following described exhibits and schedule:

Exhibit "A"—General Balance Sheet, April 30, 1925.
Schedule No. 1—Reserve Capital Fund—Securities.
Exhibit "B"—Summary of Income and Profit & Loss for the Year ended April 30, 1925.

Yours truly,
HASKINS & SELLS

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

CERTIFICATE OF AUDIT

We have audited the books and accounts of the American Institute of Electrical Engineers for the year ended April 30, 1925, and

WE HEREBY CERTIFY that the accompanying General Balance Sheet properly exhibits the financial condition of the Institute at April 30, 1925, that the Summary of Income and Profit & Loss for the year ended that date is correct, and that the books of the Institute are in agreement therewith.

HASKINS & SELLS

Appointed by the President for term of five years.

Gano Dunn, Chairman,

B. A. Behrend,	W. L. R. Emmet,	Robert A. Millikan,
N. A. Carle,	John H. Finney,	M. I. Pupin,
C. C. Chesney,	Samuel Insull,	C. S. Ruffner,
D. E. Drake,	John W. Lieb,	F. A. Scheffler,
W. C. L. Eglin,		W. R. Whitney.

Elected by the Board of Directors from its own membership for term of two years.

H. M. Hobart,	L. F. Morehouse,	Harold B. Smith,
Frank B. Jewett,	Harris J. Ryan,	W. K. Vanderpoel.

Ex-Officio

Farley Osgood, President George A. Hamilton, Treasurer,
F. L. Hutchinson, Secretary.

COMMITTEE ON AWARD OF INSTITUTE PRIZES

L. W. W. Morrow, Chairman, *Electrical World*, 10th Ave. & 36th St., New York, N. Y.

Donald McNicol, Percy H. Thomas.

COMMITTEE ON COLUMBIA UNIVERSITY SCHOLARSHIP

Francis Blossom, Chairman, 52 William Street, New York, N. Y.

F. B. Jewett, W. I. Slichter.

TECHNICAL COMMITTEES

COMMUNICATION

O. B. Blackwell, Chairman, 195 Broadway, New York, N. Y.

F. L. Baer,	Sergius P. Grace,	F. A. Raymond,
H. P. Charlesworth,	P. J. Howe,	Chester W. Rice,
L. W. Chubb,	F. H. Kroger,	J. K. Roosevelt,
C. E. Davies,	N. M. Lash,	Edgar Russel,
H. W. Drake,	Ray H. Manson,	H. A. Shepard,
R. D. Evans,	G. W. McRae,	E. B. Tuttle,
L. F. Fuller,	R. D. Parker,	F. A. Wolff,
D. H. Gage,	H. S. Phelps,	C. A. Wright.

EDUCATION

Harold Pender, Chairman, University of Pennsylvania, Philadelphia, Pa.

C. A. Adams,	M. Maclaren,	G. B. Thomas,
P. H. Daggett,	C. E. Magnusson,	R. G. Warner,
L. A. Doggett,	H. J. Ryan,	J. B. Whitehead,
Lewis Fussell,	Charles F. Scott,	W. E. Wickenden,
D. C. Jackson,	Harold B. Smith,	A. M. Wilson,
P. M. Lincoln,	R. W. Sorensen,	W. R. Work.

ELECTRICAL MACHINERY

H. M. Hobart, Chairman, General Electric Co., Schenectady, N. Y.

C. A. Adams,	G. Faccioli,	R. F. Schuchardt,
H. C. Albrecht,	W. J. Foster,	C. E. Skinner,
B. F. Bailey,	V. Karapetoff,	A. Still,
B. A. Behrend,	A. M. MacCutcheon,	A. H. Timmerman,
James Burke,	F. D. Newbury,	P. Torchio,
L. L. Elden,	J. M. Oliver,	R. B. Williamson.
	John C. Parker,	

ELECTROCHEMISTRY AND ELECTROMETALLURGY

George W. Vinal, Chairman, Bureau of Standards, Washington, D. C.

A. M. Hamann,	W. A. Moore,	John B. Whitehead,
Carl Hering,	W. E. Moore,	C. D. Woodward,
E. T. Moore,	J. A. Seede,	J. L. McK. Yardley.

ELECTROPHYSICS

J. H. Morecroft, Chairman, Columbia University, New York, N. Y.

V. Bush,	A. E. Kennelly,	Harold Pender,
R. E. Doherty,	W. B. Kouwenhoven,	C. W. Rice,
Herbert Bristol Dwight,	R. A. Millikan,	J. Slepian,
C. Fortescue,	F. W. Peek, Jr.,	Harold B. Smith,
V. Karapetoff,		J. B. Whitehead.

INSTRUMENTS AND MEASUREMENTS

A. E. Knowlton, Chairman, Dunham Laboratory, Yale University, New Haven, Conn.

F. V. Magalhaes, Vice-Chairman,

A. S. Albright,	R. C. Fryer,	L. T. Robinson,
O. J. Bliss,	C. M. Jansky,	Joseph Sachs,
H. B. Brooks,	P. M. Lincoln,	Byron W. St. Clair,
R. P. Brown,	W. M. McConahey,	G. A. Sawin,
J. R. Craighead,	Wm. J. Mowbray,	Benjamin H. Smith,
E. D. Doyle,		H. S. Vassar.

APPLICATIONS TO IRON AND STEEL PRODUCTION

F. B. Crosby, Chairman, Morgan Construction Co., 15 Belmont St., Worcester, Mass.

E. Gordon Fox,	D. M. Petty,	G. E. Stoltz,
E. S. Jefferies,	A. G. Pierce,	J. D. Wright.

PRODUCTION AND APPLICATION OF LIGHT

G. H. Stickney, Chairman, Edison Lamp Works, G. E. Co., Harrison, N. J.

W. T. Blackwell,	G. C. Hall,	F. H. Murphy,
J. M. Bryant,	H. H. Higbie,	Charles F. Scott,
H. W. Eales,	A. S. McAllister,	B. E. Shackelford,
F. M. Feiker,	P. S. Millar,	W. M. Skiff,
F. F. Fowle,		C. J. Stahl.

APPLICATIONS TO MARINE WORK

L. C. Brooks, Chairman, Bethlehem Shipbuilding Corp., Quincy, Mass.

H. Franklin Harvey, Jr., Vice-Chairman,

R. A. Beekman,	H. L. Hibbard,	Arthur Parker,
J. F. Clinton,	William F. James,	G. A. Pierce,
M. W. Day,	J. S. Jones,	H. M. Southgate,
C. S. Gillette,	M. A. Libbey,	W. E. Thau,
Wm. Hetherington, Jr.,	W. F. Meschenmoser,	A. E. Waller.
	I. H. Osborne,	

APPLICATIONS TO MINING WORK

F. L. Stone, Chairman, General Electric Co., Schenectady, N. Y.

R. T. Andrae,	L. C. Ilsley,	John A. Malady,
C. N. Beebe,	G. M. Kennedy,	D. C. McKeehan,
M. C. Benedict,	R. L. Kingsland,	W. F. Schwedes,
Graham Bright,	A. B. Kiser,	W. A. Thomas,
H. W. Eales,		C. D. Woodward.

GENERAL POWER APPLICATIONS

A. E. Waller, Chairman, Ward Leonard Electric Co., Mt. Vernon, N. Y.

A. M. MacCutcheon, Vice-Chairman,

P. H. Adams,	W. B. Hall,	T. D. Montgomery,
D. H. Braymer,	H. D. James,	H. W. Rogers,
H. E. Bussey,	A. C. Lanier,	A. F. Rolf,
R. F. Chamberlain,	W. S. Maddocks,	W. H. Timbie,
C. W. Drake,		W. C. Yates.

POWER GENERATION

Verne E. Alden, Chairman, Consolidated Gas & Electric Co., Baltimore, Md.

H. A. Barre,	Francis Hodgkinson,	John C. Parker,
E. T. Brandon,	Peter Junkersfeld,	M. M. Samuels,
H. W. Eales,	H. A. Kidder,	F. A. Scheffler,
Louis Elliott,	J. T. Lawson,	R. F. Schuchardt,
W. L. R. Emmet,	W. H. Lawrence,	Arthur R. Smith,
Walter S. Finlay,	C. O. Lenz,	N. Stahl,
N. E. Funk,	James Lyman,	B. Tikhonovitch,
C. F. Hirshfeld,	W. E. Mitchell,	W. M. White.
	J. E. Moultrop,	

POWER TRANSMISSION AND DISTRIBUTION

Percy H. Thomas, Chairman, 120 Broadway, New York, N. Y.

P. H. Chase, Vice-Chairman,

R. N. Conwell, Vice-Chairman,

R. W. Atkinson,	J. P. Jollyman,	F. W. Peek, Jr.,
A. O. Austin,	A. H. Kehoe,	A. M. Perry,
F. G. Baum,	W. G. Kelley,	H. S. Phelps,
O. H. Bundy,	L. M. Klauber,	G. C. Post,
W. S. Clark,	C. H. Kraft,	D. W. Roper,
W. H. Cole,	W. W. Lewis,	C. E. Schwenger,
M. T. Crawford,	W. E. Meyer,	A. E. Silver,
F. S. Dellenbaugh, Jr.,	Wm. E. Mitchell,	Arthur Simon,
W. A. Del Mar,	Clifford R. Oliver,	M. L. Sindeband,
L. L. Elden,	G. C. Oxer,	H. C. Sutton,
R. D. Evans,	J. C. Parker,	W. K. Vanderpoel,
F. M. Farmer,	E. P. Peck,	C. T. Wilkinson,
C. D. Gray,		R. J. C. Wood.

PROTECTIVE DEVICES

H. R. Woodrow, Chairman, 360 Pearl Street, Brooklyn, N. Y.

E. C. Stone, Vice-Chairman,

A. F. Bang,	George S. Humphrey,	W. H. Millan,
G. H. Bragg,	F. L. Hunt,	J. M. Oliver,
P. H. Chase,	B. G. Jamieson,	N. L. Pollard,
L. B. Chubbuck,	J. Allen Johnson,	D. W. Roper,
R. N. Conwell,	H. C. Louis,	A. J. Rutan,
W. A. Del Mar,	M. G. Lloyd,	C. H. Sanderson,
W. S. Edsall,	B. R. Mackey,	E. R. Stauffacher,
F. C. Hanker,	A. A. Meyer,	H. R. Summerhayes,
S. E. M. Henderson,		A. H. Sweetnam.

RESEARCH

John B. Whitehead, Chairman, Johns Hopkins University, Baltimore, Md.

Edward Bennett,	C. I. Hall,	E. W. Rice, Jr.,
V. Bush,	V. Karapetoff,	D. W. Roper,
E. H. Colpitts,	A. E. Kennelly,	C. H. Sharp,
E. E. F. Creighton,	M. G. Lloyd,	C. E. Skinner,
W. A. Del Mar,	F. W. Peek, Jr.,	Harold B. Smith,
B. Gherardi,	Harold Pender,	R. W. Sorensen.

A. I. E. E. Representatives

ON AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE COUNCIL

A. E. Kennelly, John B. Taylor.

ON AMERICAN BUREAU OF WELDING

H. M. Hobart.

ON AMERICAN COMMITTEE ON ELECTROLYSIS

B. J. Arnold, N. A. Carle, F. N. Waterman.

ON AMERICAN ENGINEERING COUNCIL

Comfort A. Adams,	*D. C. Jackson,	Charles F. Scott,
C. G. Adsit,	*Frank B. Jewett,	*C. E. Skinner,
H. W. Eales,	William McClellan,	L. B. Stillwell,
*John H. Finney,	*L. F. Morehouse,	Calvert Townley,
F. L. Hutchinson,	E. W. Rice, Jr.,	R. B. Williamson.

*Members of Administrative Board.

ON AMERICAN ENGINEERING STANDARDS COMMITTEE

H. M. Hobart, H. S. Osborne, C. E. Skinner.
L. T. Robinson (Alternate)

ON APPARATUS MAKERS AND USERS COMMITTEE

C. E. Skinner.

ON BOARD OF TRUSTEES, UNITED ENGINEERING SOCIETY

H. H. Barnes, Jr., Bancroft Gherardi, H. A. Lardner.

ON CHARLES A. COFFIN FELLOWSHIP AND RESEARCH FUND COMMITTEE

Harris J. Ryan.

ON ENGINEERING FOUNDATION BOARD

Frank B. Jewett, L. B. Stillwell.

ON JOHN FRITZ MEDAL BOARD OF AWARD

A. W. Berresford, William McClellan, Harris J. Ryan.
Frank B. Jewett,

ON JOINT CONFERENCE COMMITTEE OF FOUNDERS SOCIETIES

The Presidents and Secretaries, *ex-Officio*

ON LIBRARY BOARD OF UNITED ENGINEERING SOCIETY

Edward D. Adams, F. L. Hutchinson, W. I. Slichter.
E. B. Craft, Alfred W. Kiddle.

ON NATIONAL FIRE PROTECTION ASSOCIATION, ELECTRICAL COMMITTEE

The Chairman of the Institute's Committee on Safety Codes.

ON NATIONAL FIRE WASTE COUNCIL

John H. Finney, H. B. Gear.

ON NATIONAL RESEARCH COUNCIL, ENGINEERING DIVISION

Bancroft Gherardi, A. E. Kennelly, E. W. Rice, Jr.,
F. L. Hutchinson, *ex-Officio.*

ON SOCIETY FOR THE PROMOTION OF ENGINEERING EDUCATION BOARD OF INVESTIGATION AND COÖRDINATION

Gano Dunn, Frank B. Jewett.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ILLUMINATION COMMISSION

A. E. Kennelly, C. O. Mailloux, Clayton H. Sharp.

ON WASHINGTON AWARD, COMMISSION OF

John Price Jackson, Charles F. Scott.

ON WORLD'S CONGRESS OF ENGINEERS, PHILADELPHIA 1926. BOARD OF MANAGEMENT

Paul M. Lincoln, C. E. Skinner.

ON U. S. NATIONAL COMMITTEE OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION

Clayton H. Sharp, President, 556 E. 80th St., New York.
[6]S. G. Rhodes, Secretary, 124 E. 15th St., New York,

C. A. Adams,	H. W. Fisher,	F. D. Newbury,
P. G. Agnew,	[4]Com. C. S. Gillette,	H. S. Osborne,
[8]C. A. Bates,	[6]Gen. G. H. Harries,	Farley Osgood,
George K. Burgess,	H. M. Hobart,	L. T. Robinson,
[1]James Burke,	D. C. Jackson,	D. W. Roper,
J. J. Carty,	A. E. Kennelly,	[3]Gen. C. Mck. Saltzman,
L. W. Chubb,	G. L. Knight,	[8]H. R. Sargent,
[8]Le Roy Clark,	[5]R. A. Lundquist,	C. F. Scott,
[1]C. L. Collens, 2d,	F. V. Magalhaes,	C. E. Skinner,
W. A. Del Mar,	C. O. Mailloux,	Elihu Thomson,
A. L. Doremus,	A. S. McAllister,	[1]A. E. Waller,
Gano Dunn,	A. H. Moore,	[2]C. L. Warwick,
[16]L. L. Elden,	[8]R. W. E. Moore,	R. B. Williamson.

[1]Representative of Electric Power Club.
[2]Representative of American Society for Testing Materials.
[3]Representative of War Department.
[4]Representative of Navy Department.
[5]Representative of Bureau of Foreign and Domestic Commerce.
[6]Representative of National Electric Light Association.
[7]Representative of Bureau of Standards.
[8]Representative of Associated Manufacturers of Electrical Supplies.

LIST OF SECTIONS

Name	Chairman	Secretary
